One such platform is from Vivametric. They are a device agnostic data analytics platform that ingests, standardizes and analyzes large information data sets from both wearables and biosensor devices using a data-as-a-service model. Standardizing and calibrating the disparate device and wearable population is at the core of Vivametric's novel analytical platform. The company launched a private beta in December 2014, which will feature a platform that incorporates the Bitfit, Google fit, Google Wear, Apple Healthkit, and a number of other disparate wearables. According to President Scott Valentine, this will give Vivametrics 90-95% of the market for accelerometry. [61] This data clearinghouse will enable Vivametrics to add a comparative layer to the analysis, enriching the analytics and consumer-end experience. The algorithms and analytical processes result in unquestionable accuracy: correlation coefficients of 0.89-0.99 with 'gold standard' ActiGraph sensors. [62] The Samsung SAMI (Samsung Architecture for Multimodal Interactions) is another agnostic and open platform that processes data from multiple sources via open API (Application Programming Interface). This platform is ideally configured for the Samsung Simband, which is being provided as open-source reference architecture for health/ lifestyle wearables. The open API model of analytics will enable other developers to layer SAMI-based fitness data with ancillary data, such as food diary app data or calendar app data. [63]

The standard system architecture comprises three major logical layers: storage, query, and analysis. The data storage layer consists of a non-relational, relational, ontology, cloud storage, and 3rd party databases. Data sets will communicate with different storage layers depending on the type of sensor and captured data. [64] Data points are curated by sensor reading data, data attachment index, tag mapping, and block mappings in order for it to be retrieved quickly. Triggers, with condition information, perform specific actions when conditions are satisfied. [65] The query and analysis layer consists of the workflow engine and ontology engine. The former is involved in the scheduling and execution of workflows and processes. The latter is involved in the annotation of data sets and providing the semantic substrate to manipulate the various formats of health data sources. Moreover, it is the ontology engine that enables integration and aggregation of different data formats. [66] Finally, the application layer consists of components that are involved in the management, access, and distribution of the data. The API service components offer an easy-to-use interface for access, management, visualization, etc. [67] Figure 6, illustrates a standard system architecture featuring the API service component in the application layer.

The API open service model is even more critical in the biosensor and medical implantables/embeddable space. The real-time predictive processing of a confluence of biological data from various sources and formats will spur the digital health revolution. Combining data streams in order to deduce meaningful patterns may only be possible in an open API analytical framework. The framework can be adapted from HealthData.gov API, used to provide software developers programmatic access to the contents of the public-wide health data catalog. The API allows for search and advanced query capabilities using API-enabled

datasets, as well enable developers to build a new data catalog tool. The HealthData.gov API uses the CKAN version 2.0beta. [68] The following is an example of a dataset that could be converted into an app by a developer using this API analytical framework: The TXT4Tots Message Library datasets provide recommended text for age-appropriate nutrition and physical activity reminders. Use the Data API to build an app that sends push notifications to wearable device users with targeted reminders appropriate to the age and activity of the wearable device user. This example illustrates how the API methodology can enhance health outcomes by leveraging web and cloud architecture to increase the efficiency of health data transfer and distribution. [69]

Figure 6. Standard system architecture featuring an API open service model for the biosensor space.

Gallileo Analytics co-founder, Anna McCollister-Slipp, has called on wearable/embeddable (device) manufacturers, hospital systems, and electronic health record companies to make the data accessible to patients and developers in order to provide a more thorough digital health ecosystem. “From a technological perspective, this problem is easy to fix. We could do it this week or this month, if we chose to do it. But so far, we have lacked the political will to force or the corporate will to choose to make personal data access a priority,” said Ms. McCollister-Slipp. [70] This digital health revolution is poised to not only deliver patient-centric positive outcomes, but is also touted to deliver substantial health care efficiencies, such as improving access and lowering costs.

INTERNET OF THINGS ECOSYSTEM

“As the Internet of things advances, the very notion of a clear dividing line between reality and virtual reality becomes blurred, sometimes in creative ways”- Geoff Mulgan

The above-mentioned companies range from wearables, Internet of Things, big data analytics, and smart devices. What do these companies all have in common? They are all cogs in the same machine: components and devices in an interoperable ecosystem with a cloud backbone involved in real-time sensing, processing, and provisioning.

Regardless of the type of sensor technology, none of this fine-tooth data capturing has any consumer-end value unless it is coupled to a cloud-based analytics and provisioning. Due to the large data sets and heterogeneous objects, in order for these sensor-laden devices to have any true appreciable value to the consumer, it must be seamlessly and intelligently linked with cloud-based provisioning across interoperable access layers/gateways. Unless the devices are coupled to a larger interoperable ecosystem, such as an Internet of Things (IoT) ecosystem, the provisioning capacity of the data will be limited in scope. While wearables are currently being deployed in industries as diverse as healthcare, entertainment & media and retail, the focus of this section will be on wearables that deliver health and lifestyle provisioning. Wearables in this space have the potential to deliver personalized diet and exercise mapping on a very granular level; deliver personalized health information, thereby removing the information asymmetries between health provider and patient and in addition, deliver on-demand, real-time diagnosis and tailored-therapeutics. This analytics-enabled biosensor data can not only provide efficiencies and positive outcomes for the individual with the wearable or embeddable, but it will also provide healthcare organizations and providers with the customized analytics to deliver a tailored-approach to treatment. Insurers can use the captured data to better manage healthcare and to lower overall healthcare costs. Finally, the analytics will provide clinicians and researchers with robust, real-time safety and efficacy information during late-stage clinical trials. [71]

The IoT ecosystem refers to the interconnection of uniquely identifiable embedded computing-like devices within the existing Internet infrastructure across a wide variety of protocols, browsers, and applications. This emerging technology converged with communication technology, such as RFID, NFC, etc., along with the huge increase in Internet

Protocol address space with the advent of IPv6 and the vast storage space of the cloud. Even by conservative estimates, it is estimated that 30 billion devices will be wirelessly connected to the Internet of Things by 2020. What's more, by 2030, the average person will come into contact with 3,000-5,000 IoT objects on a day-to-day basis, [72] the lion share of which will be wearables and embeddables.

Challenges

These wearables/emdeddables will require a network architecture that is adaptable to the massive scale and dynamic nature of the Internet of Things—a planetary-scale network infrastructure. On a high-level, it must be able to mine and analyze the vast swaths of data in real-time. Conversely, on a granular level, it must be able to sense and actuate the smallest of devices with the utmost discrimination. Additional limitations in the art include a lack of standards and interoperable technologies, data mining and analytics in real-time, securing such data from unauthorized use and attacks, and finally, network inefficiencies. Novel programming, content-delivery, and network management approaches are very much needed to catch up to the fast emerging ecosystem of IoT. In terms of network management, current architecture found in the art is designed for small-scale, closed-loop networks, which are unable to communicate across these networks in real-time. These access and latency issues effectively impair the execution of the distributed tasks of sensing, computing, and actuating. There exists an essential need for novel software-defined network architectures to effectively and efficiently deliver real-time, contextually based IoT services.

As the ubiquity of network-enabled wearables grow, consumer demand for IoT products and services will surge. All of the current heterogeneous networking infrastructures will have to be integrated into a clean, seamless networking platform. Another limitation facing wearables and the IoT is its vulnerability to cyber-attacks. This is especially a concern in the area of health wearables, where big health data in relation to individuals may be compromised and trigger an assortment of health privacy issues. New security controls of legacy security processes and technology will be needed. Besides the stop-gap patches deployed from the various manufacturers, a comprehensive security life-cycle- that is contextually-aware and behaviorally-adaptive- will need to be implemented in wearable-coupled IoT networks. These new approaches center around the way security in an Internet of Things network is architected, delivered, and self-monitored.

Finally, bottlenecks and latency represent the final hurdle. Currently, in order to accommodate newly introduced objects, the network elements need software upgrades in order to deliver dynamic provisioning. Even firmware upgrades of existing objects may require a matching software change on the network elements. Such a requirement presents tremendous bottlenecks when introducing new objects or object firmware. A dynamic and elastic IoT infrastructure is necessary to circumvent these data bottlenecks. It is expected that there will be three Internet Protocol-connected devices per capita and network traffic will reach 17 GB per capita by 2018. Global IP traffic will grow at a compound annual growth rate of 21% from 2013-2018, as illustrated by figure 7. Over half of all of this IP traffic will originate with non-PC devices, such as machine-to-machine (M2M) or wearables. [73] Cloud-centric, predictive and automated provisioning and deprovisioning of IoT-linked wearables will be the key to the seamless fusion between the physical and digital world.

With the lack of uniformity in standards across various frequency bands and communication protocols, adequate wireless connectivity is vital for Internet of Things network architecture, and provisioning ability of the wearable. The wireless connectivity technologies that are predominant in the market are adequate for the purposes of the IoT network. The standard communication protocol utilizes a set of rules and standards to format and control data exchange. The two standard communication models are the OSI model and the TCP/IP stacks. Both, the model and the stack, are further differentiated into a number of informational layers, allowing for integration with scalable and interoperable networks. In the IP stack, Wi-Fi represents the link layer and bi-directionally converts bits of data, and provides data framing for wireless communication. The network layer routes data through the network and provides a unique IP address (IPv4, IPv6, etc.) to every heterogeneous object (wearables, thermostats, light switches, etc.) in the IoT network. The Transmission Control Protocol allows multiple applications to run on one device. Finally, the HTTP is the predominant application layer protocol and governs data flow and is still used to transfer web content over the Internet.

Figure 7. Cisco VNI Forecasts 132 Exabytes per Month of IP Traffic by 2018.

While a layered network implementation enables scale and interoperability, it also introduces more complexity. Internet gateways may be used to connect IP devices to the Internet by using a TCP/IP stack to restructure the simpler data flow from the local network. This enables faster and more flexible connectivity. Wearables may encompass the full range of network classes: PAN, LAN, NAN, and WAN. The standard PAN short-wave radio technology used to communicate an object with a hand-held device are Bluetooth, NFC, ZigBee, 6LoWPAN, Zwave, ANT, DECT ULE, etc. The standard LAN is the Wi-Fi based on the IEEE 802.11 standard. Until a few years ago, adding Wi-Fi connectivity to smaller, household object

would have been unthinkable; however, it is possible now due to the advances in silicone devices. Finally, the standard WANS used for the external network is 2G, 3G, 4G, and WiMax. Thus, internet gateway functionality between interoperable and distributive devices is, as imaginable, crucial to the real-time health provisioning of the wearable.

The Broad-Sweeping Implications

According to RockHealth, a stalwart in the fields of digital health accelerators and venture funding, has recently announced near \$1.9B raised for start-ups incorporating predictive analytics into their business model, from 2011-Q3 of 2014. [74] RockHealth has been instrumental in providing seed funding and access to a network of industry leaders for digital health start-ups, many of which are biosensor wearable companies that deploy predictive analytics. RockHealth claims that venture funding for biosensor wearables has increased five-fold from 2011-2013, [75] reflecting the consensus that these convergent technologies, bridging once very disparate sectors, has finally arrived to deliver life-altering outcomes. This personalized medicine revolution has begun to catalyze disruptive innovations across many different sectors of PM and an entire cadre of legal issues has emerged, from patents to privacy.

What are the implications of the new post-grant proceedings of the America Invents Act, which are being used to invalidate previously issued weak patents? The weakening of software patents by the recent Supreme Court decision in *Alice* will also have an undeniable impact on the biosensor/wearable patent landscape, especially with respect to the back-end. What about the fee-shifting provisions of the proposed troll reform legislation being mulled over by Congress? This could undoubtedly have an effect on the commercialization of digital health start-ups. Moreover, the aggregation and distribution of patient data triggers all sorts of privacy issues under HIPAA. On the other hand, Obamacare, as polarizing as it has been, could serve as a legislative accelerator for start-up digital health companies, for these digital health start-ups could be at the forefront of integrating personalized health data with hospitals and proxy systems. The transitioning of medical records into an integrated electronic system that could serve as a platform for a multi-disciplinary approach to healthcare is a legislative priority of the law, after all. What's more, will the patent troll reforms being mulled over in Congress, namely the fee-shifting provisions, have any impact on digital health landscape? In particular, will digital health start-ups be hesitant to go through seed-funding, research, and commercialization in lieu of looming, incendiary trolls? Not to mention, will digital health start-ups be hesitant to enforce their patents through litigation knowing that losers may be responsible for the legal fees of the winner under the fee-shifting provisions currently being debated? If patents are not enforced, will there be enough incentives for innovation? Finally, the groundswell of support for an open-source technology environment will be explored and whether or not this growing sentiment can be reconciled with a protective patent strategy. All of these potential hazards need to be accounted for in developing a strategy for navigating through the tricky biosensor/wearable landscape.

Figure 8. U.S. wearable device market.

VALUE OF PATENTS

The market forecasts are mirrored very closely by the patent landscape, based on wearable device market data and U.S. patent issue data from the U.S. Patent & Trademark Office (Figures 8 and 9), suggesting the value of patents as drivers of innovation and market dominance. [76] Having a thorough understanding of the patent landscape can help identify emerging areas of innovation within the biosensor/wearable space, even prior to being deployed into consumer form factor products. Building a patent portfolio with broad, robust patents that cover emerging areas of innovation within the space that address fundamental needs is, crucial for all digital health start-ups as well as established bell-weather. In addition to launching products with innovational features that are legally protected with market exclusivity, these strategies may also enable a digital health company to engage in a lucrative licensing program. Finally, it can serve as a defensive initiative, whereby competitors are blocked from entering into these newly found niches in the overall space, or from preventing competitors from designing-around.

The current wearable tech market is dominated by a few devices, and by an even fewer number of stalwart companies. It is often described as a “mass niche” by industry experts, despite the \$3 billion in revenue forecast for this year. [77] Large tech-conglomerates are in the midst of building their wearable tech patent portfolios. In 2013, Google was awarded 2,000 patents, nearly double the number of all patents previously awarded combined. According to IFI CLAIMS 2013 top 50 US Patent Assignees, Google ranked 11th on the list this year with 1851 patents. [78] Of these patents, the trending shares are increasingly related to wearable tech, shifting Google’s patent portfolio from the litigation-exposed smart phone market to the

emerging wearable tech market. Figure 10, indicates the top U.S. patent filing companies for the past decade, and their share of the overall wearable patent landscape. Strategically, Google has opted to adopt Apple's model for technology acquisition: buying patents crowding a tech landscape in order to get complete vertical control of an entire technology platform. This is in contrast to Google's approach to their smart phone patent portfolio, where licensing and cross-licensing deals were in place for various proprietary positions. [79]

U.S. Patents for Smart Devices by Segment (2003-2013)

Note: Cumulative filings do not equal total filings due to several patents containing more than one segment

Source: U.S. PTO, Hanover Research analysis

Figure 9. U.S. patents by wearable segment.

During its infancy stage, interoperability and industry standards will influence standard-essential patents and FRAND-licensing patents (Fair, Reasonable and Non-Discriminatory). Patents that cover technology verticals that are essential for the implementation of a given standard will be licensed on FRAND terms, much like the mobile and semiconductor industry during its infancy stage. This is to ensure interoperability among various components and devices, across different networks, while still providing the necessary incentives for continued innovation in the wearable tech space. [80]

Top U.S. Patent Filing Companies for Wearable Tech, 2003-2013

Figure 10. Top tech companies and their share of the overall wearable patent landscape. (<http://www.hanoverresearch.com/insights/the-rise-of-the-wearable-tech-market/?i=food-beverage>).

Motorola Mobility sought from Apple, 2.25% of net sales on all iOS products (amounts to roughly \$12/iPhone) that use essential industry standard patents (video-streaming and Wi-Fi technology, in particular). [81] Apple, however, believed that these terms were not consistent with FRAND terms and accused Motorola of seeking egregiously excessive payments on essential technology for mobile devices. District Court judges have ruled that Motorola was obligated to FRAND license the patented technology under the contractual agreements between Motorola and the standardization issuing organizations, namely the ETSI and IEEE. This has called Google's patent strategy of acquiring Motorola Mobility for \$12.5 billion into serious question; vertical acquisition or developing in a nascent tech sector must be weighed against industry standardization processes and possible FRAND licensing obligations. [82] Despite much of the Motorola Mobility portfolio being labeled 'FRAND', Google has still decided to retain much of the patent portfolio, as it prepares to sell off Motorola Mobility to Lenovo. [83] Any basic benchmarks and methodologies used in developing a FRAND, particularly in the field of smart wearable technology, must strike the most equitable balance between maintaining innovation incentives and royalty stacking. In a recent development that may have far-reaching implications on how IT-related patents are licensed, Qualcomm's model of aggressive licensing is facing a governmental investigation for alleged monopolistic practices in China, in addition to ongoing regulatory investigations in the U.S. and Europe. The IEEE, the electronics standards group that establishes protocols so technology can be used across devices, may adopt a proposal to prevent excessive fees charged for licensing technology in Wi-Fi standards now essential to connect all devices- hand-held or not- to the Internet. The measure would limit patent owners from getting courts to block product sales of companies using the technology without paying what has amounted to exorbitant fees. This standard, if adopted, could have far-flung implications on licensing models across a wide swath of technology, bioinformatics driven devices included. [84]

Patent Strategy

Protection for these strategic business assets will at its core, include a robust patent portfolio with a broad family of patents and an accompanying patent leveraging program. The beguiling jewel of any leveraging program will be its licensing and assignment program. Any leveraging program in this space will incorporate a four-step process: (1) compiling a target list of infringers or potential infringers within the niched space; (2) preparing claim charts, itemizing how infringing product features read or potentially read on every element of at least one claim; (3) conducting a patent valuation; and (4) negotiating a license/assignment. [85] The terms of the licensing/assignment agreement will vary depending on the targeted companies, and whether the targeted companies are actively infringing, or operating tangentially to the outer boundaries of the scope of the patent claims. Terms will also depend on whether it is an exclusive license or a non-exclusive license; and whether assignees are whole or partial.

Step 1

In compiling a list of targets, priority should be given to targets that are actively infringing every single element of at least one claim in the patent. Market-efficiencies may call for allowing the target to continue commercialization, provided they engage in a “stick” agreement, versus a “carrot” agreement. By being in a state of active infringement, this provides tremendous leveraging power to the patent owner and allows for certain terms to be dictated in the favor of the patent owner, hence the term “stick”. Moreover, provided that the specification of the parent application is expansively constructed, additional continuation applications may be filed that claim priority to the earlier parent application, and have claims that are drafted that read on currently commercialized product. This type of post facto infringement targeting is dependant on the newly drafted continuation claims finding support in the specification of the earlier parent application. This strategic insight underscores the importance of drafting the parent specification and claims narrow enough to navigate through the crowded patent landscape, while still being expansive enough to maximize value, deter design-arounds, and foresee emerging trends in order to leverage strategic positioning.

Companies that are not actively infringing, but operate in a space that is tangential to the scope of the patent, should also be targeted. Market efficiencies may dictate that a company adopts or piggy-backs on new features that are covered by the patent, and should enter into a licensing agreement with the patent owner in order to capitalize on this protected feature and potential market. The company already operating in the space may have the requisite know-how on reducing the concepts covered by the claims into a commercially-viable embodiment, with more efficiency than the owner or assignee of the patent. In such a case, “carrot” agreements may be entered into, which may have more market incentives for the licensee, since active infringement is not present.

Step 2

Once targets are compiled, claim charts and infringement reports are created, aligning distinct product features of the potentially infringing product against distinct elements of the patent claim. An additional column provides the claim construction, whereby key elements within the claim are defined, preferably defined as broadly as possible within the constricts of the specification in order to trap the product features of the potentially infringing product. In

addition to serving as the basis of an infringement analysis and licensing negotiations, it can also be instrumental in providing free and clear pathways to patentability and validity in order to help: (1) determine portfolio coverage and gaps; (2) discover product options that weren't earlier apparent; and (3) serve as a precursor to a freedom-to-operate framework, paving the way for commercialization, leveraging, and mitigation of litigation risk. Given the growing competitive landscape of the wearable market, litigation rates will likely mirror other tech sectors [86], underscoring the strategic value of having a panoramic view of the patent landscape.

Step 3

Prior to committing into commercialization or licensing efforts, a rigorous valuation of the patent or family of patents will need to be performed. There are three classic valuation methodologies that are used: (1) cost; (2) income; and (3) market. The cost approach aims to determine the value of the patent by determining the cost of acquiring or developing an equivalent approach. [87] The income approach aims to determine patent value by forecasting future revenue over the course of the life of the patent. The estimated future revenue is then discounted to arrive at a single net present income. [88] The market approach aggregates transaction data of similar or comparable technology in order to yield a valuation.

The market approach yields the most accurate estimate, provided that information of similar or comparable transactions are available. [89] Unfortunately, patent transactions operate in secondary markets and are often confidential. Even if one was privy to certain patent transactions, it is exceedingly difficult to find comparable transactions with analogous IP and market parameters. [90] Likewise, the other approaches are also replete with flaws. Subsequently, in order to perform a thorough assessment and arrive at a fair value, its probably best to use a hybrid approach, whereby distinct metrics spanning across all three methodologies are accounted for: (1) remaining years in the patent life; (2) number of claims, especially independent claims, and the breadth and strength of these independent claims; (3) size of patent family/priority analysis; (4) patent validity analysis; (5) foreign status; (6) and the number of forward and reverse references; (7) technology/product review- parameter differentials between patented product and substitute product; and (8) market coverage analysis/sales forecasts. [91]

If comparable transactions aren't available and the patented product has been commercialized and substantive financial data is available, then the hybrid approach to valuation referred to as the comparative advantage valuation model may be used to derive a fairly accurate patent valuation. Given the patent segmentation spanning across individual wearable and biosensor products, the CAV model may be the optimal means of valuation. The CAV model can accurately derive a base patent value for each patent covering distinct components and parameters of individual products. Adapting Ted Hagelin's CAV analysis of a hypothetical case study, we will similarly conduct a valuation analysis on a series of hypothetical patents covering various components of a hypothetical wearable/biosensor product.

Hypothetical Valuation Case Study

OpticProbe, Inc. is a start-up firm specializing in the research, manufacturing, and distribution of biosensor and wearable devices. Its flagship product is the biosensor device, YouSense. YouSense binds selective biomarkers using embedded nano-tube sensors with receptor substrates that produce an optical change upon binding. This optical change is then translated into a quantifiable digital signal by a transducer component, and then processed by an analyzing component and cloud-based back-end analytics in order to identify the biomarker. OpticProbe operates in the burgeoning subfield of nano-biosensor devices, with a total of ten firms with a total market value of \$850 million.

Step 1

The first step involves identifying the patents and its associated device parameters. For instance, the competition parameter for the sensor component is sensitivity; how much biomarker is needed in a given unit of sample in order to trigger a reliable detection and a robust signal. The competition parameter for the transducer is the translation fidelity or conversion rate; how much deviation or spill-over is there between sensor input and transducer digital signal output. Finally, the competition parameter for the device and back-end processing components is the provisioning rate; how much latency exists in the real-time data provisioning of the analytics. Once competition parameters are identified, the associated patents within the patent portfolio need to be identified. A quick survey of the OpticProbe portfolio reveal that patent '234 is associated with the sensor component and sensitivity parameter; patent '567 is associated with the transducer and conversion rate parameter; and patent '890 is associated with the processing components and the provisioning rate.

Step 2

The next step is to research parameter values of the product and substitute product in order to determine the relative competitive advantage in comparison to other patents incorporated in the associated product. The table below includes the hypothetical parameter values and hypothetical competitive advantage for an average nano-biosensor and YouSense.

The technical Intellectual Property value is first determined by subtracting the tangible asset value from the total market capitalization value. The remaining value, total intangible asset value, is parsed from the technical Intellectual Property value, by dividing the sales, general, and administration expenses by the SG&A minus advertising plus business processing spending. This value is then further multiplied by the total intangible asset value percentage to yield the intangible asset percentage $[(\$20 \text{ m}/\$20 \text{ m} + \$10 \text{ m}) \times (100\%-15\%)] = 56.67\%$. Finally, the technical Intellectual Property Value is derived by subtracting the intangible percentage from the total intangible percentage, and then multiplying the intellectual property value percentage by the net present value $[(85-56.67) \times 150\text{m}] = 84\text{m}$. This year's sales records, projected growth, forecasted sales, remaining patent term, and present discount rate are all required to arrive at the net present value of \$150m, and ultimately with a final technical IP value of 84m. [92] The base value for each patent corresponding to a unique product parameter is 22.7m, 27m, and 63m, respectively.

	Sensor Amount/unit for threshold detection	Transducer Deviation between sensor input and signal output	Processor Latency (seconds) of data provisioning
Patent	‘234	‘567	‘890
Substitute Product Parameter Values	500	0.25	0.8
YouSense Parameter Values	250	0.10	0.2
Base Competitive Advantage (YouSense PV-Product PV)/Product PV	0.5	0.6	0.75
Relative Competitive Advantage (Base Competitive Advantage/Total Base Competitive Advantage)	$(0.5/1.85)=$ 0.27	$(0.6/1.85)=$ 0.32	$(0.75/1.85)=$ 0.41
Base Value RCA x 100 % (Technical Intellectual Property Value)	$(27\% \times 84 \text{ million})=$ 22.68 m	$(32\% \times 84 \text{ million})=$ 26.88 m	$(75\% \times 84 \text{ million})=$ 63 m

Step 3

The base values then have to be discounted by their corresponding risk value. IP risk factors include obsolescence of rights, loss of rights, and strength of rights. Obsolescence of rights is the measure of risk against the patent becoming functionally obsolete prior to the expiration of the product life cycle. [93] Obviously, obsolescence, loss of rights due to post-grant events, and the neutering of patents with crafty design arounds, all have tremendously devaluing effects on the value of the patent. This potential devaluing risk can be priced into the overall valuation by multiplying the base value of each patent by $(1 - \text{total IP risk factors})$. [94] For instance, let us suppose that OpticProbe patent counsel have discovered a publication on nano-biosensors that predates the priority date of the ‘234 patent and believes that there is a 5% chance of the ‘234 patent being invalidated in a post-grant proceeding. Also, let us suppose there is an additional 5% chance that competitor engineers would be able to design around the sensor optical output by designing a sensor that creates an electrical output upon binding of the receptor substrate. In this scenario, the total IP risk factor for ‘234 is 10%. For the purposes of this case study, let us assume that the remaining patents retain the same risk factor. The following table illustrates the final adjusted base value for all three patents, adjusting for their respective patent risk factors.

As it has been illustrated through this hypothetical case study, the ‘890 patent is the most valuable patent in the portfolio, valued at an adjusted \$56.7m. As one can imagine, the provisioning aspects of a biosensor/wearable product would be expected to be the most valuable component/parameter of such a product. Without real-time analytics and provisioning, these devices serve very little use to patients or consumers. The biological recognition element that the signal output and analysis is derived from may, no longer be representative of the current physiological state due to the back-end latency. Patents ‘234 and ‘567 are valued at \$20m and \$24m, respectively. Now that we have adjusted base values for the three patents in the OpticProbe YouSense portfolio, what are some strategic steps to leverage this valuation?

	Sensor Amount/unit for threshold detection	Transducer Deviation between sensor input and signal output	Processor Latency (seconds) of data provisioning
Patent	‘234	‘567	‘890
Adjusted Base Value Base Value x (1- total risk factor)	22.68 (1- 0.10)= \$20.412m	26.88 (1-0.10)= \$24.192m	63 (1-0.10)= \$56.7m

IMPACT OF ALICE AND MAYO ON IP

The Supreme Court decisions in *Bilski*, *Mayo*, and more recently in *Alice*, have resulted in a legal sea change in terms of patent subject matter eligibility. Moreover, the recent reforms of Congress in the America Invents Act, has dramatically changed the landscape of patent law. Figure 11, depicts these developments in a timeline fashion. One need not look any further than the changes in the first to invent system- the U.S. being the lone holdout- to a first to file standard. Aside from the file-to-file changes, there are a number of other prosecution changes that the AIA has introduced, such as making it easier to invalidate applications and patents via a newly expanded suite of pre-issuance and post-grant proceedings. The USPTO has codified these judicial and legislative changes into examination guidelines that may be found in the Federal Register or the Manual of Patent Examination Procedure. Neither of which are helpful, without some prosecution guidance helping navigate the complex legal labyrinth that is patent prosecution and enforcement.

Figure 11. Timeline of recent developments in patent law. (Brougher, Joanna, and Konstantin Linnik. "Patents or Patients: Who Loses?" *Nature Biotechnology* 32 (2014): 877-80. Web. <http://www.nature.com/nbt/journal/v32/n9/fig_tab/nbt.3005_F1.html>).

Patent Prosecution

All of these changes have one obvious effect: making it more difficult to get a patent, most particularly in the fields of software and biotechnology. Bioinformatics, laying at the intersection of these fields, is most exposed to the litany of prosecution reforms. In the wake of these reforms, there are a number of bioinformatic parameters associated with wearable back-

end analytics that have been found to be worthy of protection by the PTO, namely the software tools for biological data mining, visualization, pattern recognition, sequence alignment, modeling, predictive tools, etc. Additionally, the mechanical and biochemical sensors, along with the small factor forms of wearable devices have been found to be patent eligible, even under the constraints of the new regime. The key is to identify these constraints, and circumvent them with sound diligence, claim drafting, office action responses, and enforcement.

IP Due Diligence

The first step is to assess the current patent portfolio of the company. Portfolios of patented technology and licensed technology should be categorized into different competition parameters. For instance, the OpticProbe YouSense portfolio could be categorized into several parameters: form factor, display interface, sensor sensitivity, signal transduction, real-time analytics/provisioning, data mining, recognition, structure modeling, predictive modeling, dashboard alerts/visualization, app interfacing, etc. Competition parameters should be further categorized into “definitely utilize”, “likely utilize”, and “not likely utilize”. Product features of YouSense should be aligned with patent claims of the associated patents in the portfolio, categorized by parameter and utility. Categorized claims without any product features or an underrepresented amount of features represent areas in which OpticProbe may decide to roll-out a new and improved iteration of YouSense embodying these new features. [95] If it is consistent with OpticProbe’s product development strategy, they may want to roll-out other wearable products that embody these claim features. Crafting patent strategy to align with OpticProbes business plan is crucial. Conversely, the empty parameter bins- competition parameters with a lack of associated claims- should be seen as an opportunity to leverage the portfolio by filing additional continuation claims, claiming priority to the original parent filing, provide the scope of the continuation claims can find complete support in the parent filing. Filing continuation claims can have the benefit of gaining a market foothold on an emerging feature, or merely, play a defensive role- blocking potential competitors from developing and commercializing the feature. Having a robust portfolio with broad claims provides OpticProbe with significant competitive advantages, not the least of which is the luxury of engaging in a potentially lucrative licensing program.

Claim Drafting in the Wake of *Bilski*, *Mayo*, *Myriad* & *Alice*

With the ever-changing landscape of patent prosecution, in the wake of *Bilski*, *Myriad*, *Mayo* & *AIA*, one cannot underscore enough the competitive value of having a sound claim drafting strategy. Any sound strategy would start with frequent inventor and examiner interviews. Interviews will bring the high-level picture of the invention into focus, and additionally, place the granular-level details into proper context. Having this high-low level or top-down perspective of the invention will underlie more value-laden, tailored claims that cover the breadth, as well as the more nuanced elements of the invention. It has been demonstrated, at least anecdotally, that frequent interviews with the examiner often facilitate a more streamlined prosecution pipeline. [96] This is presumably due to the fact that subject matter issues become elucidated earlier in the pipeline, enabling the prosecutor to adjust claim

language to fit within subject matter eligibility guidelines in lieu of the recent case law and legislative reforms.

Patentable subject matter has been the most contentious issue in patent law, polarizing people from kitchen tables in the Bible belt, all the way to senate committee hearings on the Hill and the hallowed halls of the Supreme Court. At the heart of this debate, is whether certain claims, particularly method claims, were attempting to monopolize mere abstract ideas, such as algorithms and DNA, without any tangible implementation or intervening step. *Bilski v. Kappos* (2010, Supreme Court) and *Mayo Collaborative Services v. Prometheus Laboratories* (2012, Supreme Court) are two major recent developments regarding patentable subject matter. *CLS Bank v. Alice* (2014, Supreme Court) represents the third leg of the subject matter eligibility trilogy. The Supreme Court is unified in all three cases: the claims must go beyond the natural occurrence/principle/phenomenon/law; naturally occurring things are not patent eligible. In *Mayo*, in light of *Bilski*, the Supreme Court reaffirmed the shortcomings of the machine-or-transformation test, and determined the patent under consideration to be ineligible since it attempted to monopolize a mere correlation that is found in the law of nature. [97] In *Myriad*, the Supreme Court ruled that, while isolated genomic DNA is not patent-eligible (naturally-occurring) under section 101 of the Patent Act, cDNA (resulting from the intervening step of reverse transcription) is. [98] Most recently, *Alice*, has reinforced this patent eligibility standard, in the context of computer software and business method claims. The Supreme Court, in *Alice*, applied the two-prong patent eligibility framework from *Mayo* against the computer-implemented method claims at issue, and held them ineligible. The Court ruled that the claims were (1) a natural phenomenon, abstract idea, etc.; and (2) the claims do not recite sufficient additional elements to transform the natural phenomenon, abstract idea, etc. [99] The Court held that, “merely requiring generic computer implementation” did *not* “transform that abstract idea into a patent-eligible invention.” *Alice* ushers in, yet another watershed moment- claims to a method, a computer system configured to carry out the method, and a computer-readable medium containing program code for performing the method all fell invalid under Section 101 (subject matter eligibility). This line of jurisprudence could have a significant impact on the validity of bioinformatics applications.

With respect to YouSense, the novel and non-obvious aspects that deal with providing technical solutions to consumer demands, will fall outside of the 101 hazard, and will be patent eligible. Emphasizing these aspects in the claim and specification is crucial, especially regarding the back-end analytics and provisioning portions. It’s the back-end bioinformatic tools that are the most exposed to the risk of 101 ineligibility. Claims covering the back-end will need to be drafted in the context of a substantive computer implementation that results in a tangible, transformative outcome. The following are some of the claim drafting best practices in capturing Intellectual Property for software-implemented, bioinformatics-related innovations in a post-*Alice* landscape. According to the preliminary examination instructions issued by the USPTO in the wake of the *Alice* decision, claims that are drawn to software or computer-implemented methods should have meaningful limitations beyond generally linking the use of an abstract idea to a particular technological environment. [100] Claims that require no more than a generic computer to perform generic computer functions- that are well understood, routine and conventional activities previously known to the industry- will not be patent eligible in this new post-*Alice* era. [101] In terms of specific approaches, drafting multiple independent claims, each embodying different ways to perform the computer-implemented method, is sound strategy. However, as a word of caution, there will always be a

risk of a restriction requirement- a request to elect claims that pertain to the same invention, and cancel the set of claims that pertain to a wholly, different invention. Notwithstanding, potentially receiving a restriction requirement will have significantly less adverse patent consequences than a section 101 eligibility rejection. Additionally, system, computer-readable medium and computer-implemented method claims with greater detail and clarity-without losing any strategic value- will be crucial in avoiding 101 rejections. Moreover, including a particular machine or particular transformation, which implements or integrates the abstract idea, is critical. Finally, add features that are more than conventional, routine, insignificant extra-solution, or simply a mere field of use. The following hypothetical claims drawn to YouSense shall serve as an illustrative guide.

A computer-system-implemented method, the computer system having at least one programmed processor to implement the method, the method comprising:

- *continuously collecting and processing biomarker data with respect to an individual from a wearable sensor device;*
- *the computer system—*
 - (i) obtaining physiological information for the individual based at least in part on output from a contextual sensor; and*
 - (ii) based on physiological data collected from the wearable sensor device, patterns from user logged history, and other contextual information, determining a recommendation for the individual.*

A non-transitory computer-readable medium storing instructions that, when executed, cause a wearable monitoring device to:

- *receive biomarker data transmitted by a device worn by the user, measuring biomarker levels of the user and detected by the device;*
- *receive contextual data transmitted by a device worn by the user, environmental cues of the user, along with activity levels of the user and detected by the device;*
- *cause real-time display presence of a first indication of the biomarker data on a first display of a dashboard app and a second indication of the contextual data on a second display of the dashboard app; and cause a recommendation to the user via a text-crawl in at least one dashboard display, text message, e-mail message, or any other form of secure communication.*

Notice the detailed steps in the computer readable medium claims versus the computer-implemented method claims. This may have been necessary as a way to design around or not encroach on a crowded prior art space. Dependent claims will refer to each of these claim sets, further adding limitations and alternative embodiments. Apparatus and system claim sets will also be included to round out the metes and bounds of the invention. Finally, a descriptive specification- with high-level system diagrams and flow diagrams- will refer to the diagrams in granular detail and provide exemplary support for the claims. Once applications have been filed, the first office action response is typically delivered within a year of filing. If patent eligibility issues are raised by the Examiner, it is imperative to first argue that the supposed “abstract” idea is not “abstract” within the meaning of the *Alice* decision. *Alice* rejections predicated on an abstract concept of recent origin- such as small-factor sensors, real-time data mining and provisioning, etc.- should be overcome by arguing that these concepts are not long-prevalent and fundamental within the meaning of *Alice*. In other words, they are not abstract concepts, such as risk hedging or intermediated settlements, both of which are concepts that

have been entrenched in financial systems around the world since time immemorial. [102] Alternatively, express limitations in the claims should be pointed out, which would run counter to any Examiners contention that the claims merely recite an abstract idea and instructions on how to apply it. Another often misconstrued holding of *Alice* has been that all method claims that recite computer implementation will be scrutinized for an *Alice* rejection. However, it is important to remember that only claims reciting abstract ideas will be subject to the *Alice* inquiry; claims not drawn to abstract ideas- not fundamental or long-standing- will not trigger the inquiry, irrespective of containing computer implementation language. [103] In the six months following the *Alice* decision, Examiners have issued a number of *Alice* rejections, anchored on the notion that a computer implementation is per se patent ineligible. Despite the examination guidelines in place, Examiners may still need to be reminded of their burden of proof and the two-prong analysis of *Alice*. The following is an excerpt from a recent *Alice* rejection issued by an Examiner in reference to a software-related invention; note the circular fallacy. [104]

Claims... are rejected under 35 U.S.C. 101 because the claimed invention is directed to non statutory subject matter. In the instant invention, the claims are directed towards the concept of... [This] is considered a method of organizing human activities, therefore the claims are drawn to an abstract idea. The claims do not recite limitations that are "significantly more" than the abstract idea because the claims do not recite an improvement to another technology or technical field, an improvement to the functioning of the computer itself, or meaningful limitations beyond generally linking the use of an abstract idea to a particular technological environment. It should be noted the limitations of the current claims are performed by the generically recited processor. The limitations are merely instructions to implement the abstract idea on a computer and require no more than a generic computer to perform generic computer functions that are well- understood, routine and conventional activities previously known to the industry. Therefore, claims... are directed to non-statutory subject matter.

Patent enforcement strategies in bioinformatics will require considerable rethinking as well, in light of all of the seismic changes in the landscape of patent law. Most notably, how should a start-up or a young, fledgling tech company, such as OpticProbe, enforce their patents in the face of alleged infringement. Conversely, how should a company, like OpticProbe, enter a tech consumer space riddled with so-called patent trolls? After all, what good are robust, iron-clad claims, if you don't have a comprehensive enforcement strategy in lieu of all of the recent developments in law and public policy?

Just a decade ago, life science companies with core technology revolving around bioinformatics tools were weakly anchored to IP holdings. This has largely been due to the fact that much of the commercial offerings integrated public domain tools and data structures that weren't proprietary in nature. Moreover, IP budgets have traditionally been relegated to products that weren't tethered to back-end tools- with questionable proprietary value- and to products with more distinct boundaries and clearer revenue streams. There has been a shift in sentiment over the past decade. This has largely been due to three major events: (1) the USPTO's decision to allow expression sequence tags in its utility as probes to be patentable;

(2) the *State Street* decision, whereby the Supreme Court ruled that tangible applications of mathematical algorithms and business methods, as well as data processing, and computer programs, were patentable; and (3) the explosion of high-throughput methods for sequence and data gathering. [105] Leading this trend in patenting bioinformatics inventions is none other than IBM; with several thousand patent filings in a burgeoning portfolio subclass. [106] This should be a signal to the proprietary value of bioinformatic inventions. IBM, as well as other life science and IT companies are all jumping on the bandwagon; attempting to all plant their flag in this relatively uncharted territory. As of 2012, there were 90,064 bioinformatic patents- a dramatic rise from the end and turn of the century. [107] There has been a steady state of patenting activity from 2006 and 2011, and a sharp rise in 2012, which is forecasted to continue to rise into the following decade. This is reflective of industry trends and the current renewed interest in code, algorithms, network architecture, cloud provisioning, and small form-factor devices. Despite the amorphous standards for an abstract idea under *Alice*, recent patenting activity has nevertheless centered on algorithms, methods, and database methods that might be specific to handling life sciences data. In terms of the biochip and biosensor space, the space is still relatively immature from a patent perspective; only 1,800 of the 90,064 patents are related to biochip manufacturing and use. [108] Getting in on the game early provides significant strategic advantages, namely excluding competitors and positioning themselves for favorable leveraging opportunities. However, without sound enforcement strategy, the painstakingly built portfolio could be potentially worthless.

Licensing

The first enforcement tool has to be leveraging the current portfolio, by way of licensing and acquisitions/sales. Licensing in bioinformatics is segmented; with some companies exclusively licensing software tools; others license access to databases; while others license devices, etc. [109] On one hand, the diversity of market participants can make it difficult to draft claims in anticipation of competitor positioning. However, on the other hand, this dizzying licensing array should embolden executive committees and directors across the country to expand their portfolio in the direction of algorithms, software tools, interfaces, computer-implemented methods, etc.

In the competitive world of bioinformatics it comes extremely important for a company, whether start-up or Fortune 50, to have a well-developed IP portfolio that can add strategic value to a company. A company should align its potential IP with its business strategy to ensure that any IP that it is targeting flows with its current business strategy. One such strategy is for engaging in a licensing program. The strategic value stems from the fact that risks can be shifted to the licensee, from manufacturing to marketing. Risks are shifted in proportion to the exclusivity of the license, as well as overlap in markets between licensor and licensee. Some key clauses in any term sheet between a licensor and licensee will include license scope, enforcement rights, future prosecution, and ownership of improvements, liability, indemnification, warranties and representations. [110]

Currently held patents can be licensed out as a steady stream of revenue or used to cross-license technology proactively or in reaction to allegations of infringement.

Licensing can bring in a flow of capital to a company and help to build a patent portfolio. For example, Qualcomm has used licensing agreements as a core element of its business plan

and collected over \$30.5 billion during the last five years in licensing fees alone. [111] There are two basic types of licensing: exclusive and non-exclusive. An “exclusive license prevents the patent owner (or any other party to whom the patent owner might wish to sell a license) from competing with the exclusive” license holder with the licensing agreement setting forth the terms of the geographic region of use, length of time of license and even the field of use”. [112] A non-exclusive license allows the grantor of the license agreement to also use the technology. It would behoove a company seeking to license a patent to look for an exclusive patent license because it would prevent a competitor from also practicing the same licensed technology. It is no secret that a small or start-up biotechnology firm can rely on exclusive licensing rights to ensure access to high-risk capital and increase its competitiveness. [113] However, in the case of OptiProbe’s licensing of patents related to the YouSense technology, it would make sense to enter into non-exclusive deals that are drafted narrowly in terms of scope, both temporally and geographically. This strategy may allow OptiProbe the opportunity to license the patent to others, across the spectrum, to generate more revenue.

In reviewing licensing in bioinformatics, one must be cognizant of different licensing schemes across a range of technologies, including software licensing, medical device licensing, data licensing, and licensing systems. Licensing royalty rates in bioinformatics can vary based on which technology sector the IP is based. For example, electrical and chemical patent royalty rates tend to be lower at a reported approximate of 4.25% of the product in comparison to a pharmacy patent royalty rate of 7.0%. [114] Royalty rates are conventionally determined according to the 25% Rule, which stipulates that a licensee only pays a portion of the profits to the licensor, due to the additional costs and uncertainties incurred by the licensee in converting the technology to revenue. [115] The rate is calculated by multiplying the expected operating profit margin percentage for the product embodying the IP at issue, by 25% in order to arrive at the estimated royalty rate. [116] The 25% Rule can be advantageous when trying to determine the royalty rate for infringements of new technology as industry standards on licensing may not have been developed. With respect to OptiProbe’s licensing scheme, royalty rates between 4-7% may be reasonable based on the earlier stated projected financials. As a bioinformatic company seeking a “stick” license through a demand letter against an accused infringer, OptiProbe may seek the higher end of this royalty range, whereas, the lower range may be more appropriate in a “carrot” proposal targeting a company who may be projecting into the biosensor embeddable space. Depending on the specific area that a bioinformatics patent was aimed, the royalty rate and licensing scheme can vary drastically. For example, a license can be provided for free for non-commercial, academic institutions, and personal use, but for purchase by commercial entities for a one-time set up fee plus an annual fee per user. [117] This would be an example of a non-exclusive license with an open source component stemming from a university. Another example of a licensing comes from the National Institute of Health (NIH), which is specifically aimed at start up companies. The NIH has two licensing options aimed at “minimizing barriers to entry faced by start-up companies under exclusive licenses and provide a structure that encourages and supports the commercial development of early stage NIH and FDA technologies”. [118] The program offers either an exclusive evaluation license with a \$2,000 execution fee or an exclusive commercialization license with includes tired upfront execution royalties upon certain events, a set earned royalty rate of 1.5% and a set sublicensing royalty rate of 15%. [119] In a recent development that may have far-reaching implications on how IT-related patents are licensed, Qualcomm’s model of aggressive licensing of royalty stacking and coercive cross-licensing is facing a governmental

investigation for alleged monopolistic practices in China, in addition to ongoing regulatory investigations in the U.S. and Europe. The IEEE, the electronics standards group that establishes protocols so technology can be used across devices, may adopt a proposal to prevent excessive fees charged for licensing technology in Wi-Fi standards now essential to connect all devices- hand-held or not- to the Internet. The measure would limit patent owners from getting courts to block product sales of companies using the technology without paying what has amounted to exorbitant fees. This standard, if adopted, could have far-flung implications on licensing models across a wide swath of technology, bioinformatics driven devices included. [120]

Patent acquisition is another way that a company can build its patent portfolio without having to actually invent the subject matter of the patent or engage in licensing. In patent acquisition a company will buy the rights to the patent from the owner of the patent, whether it is an entity or the actual inventor. When looking to acquire patents, the strategic value of the patents being purchased and the company's business plan should be considered. In order to acquire certain patent rights, a company can either directly contact the owner of the patent or work through a third party broker in order to acquire the rights. Use of a brokerage to acquire rights will cost either a flat fee or hourly rate and a success fee if the sale is consummated. A potential benefit to patent acquisition or even patent application acquisition is that the patent acquired or the granted patent from the patent application acquired previously can then be licensed to other companies/individuals in order to bring in more revenue. Moreover, it can be used as a tool for avoiding costly litigations; such was the case in twitters acquisition of IBM's 900 or so patents covering the efficient retrieval of uniform resource locators, for presenting advertising in an interactive service, and for programmatic discovery of common contacts. In a bulk-acquisition of OptiProbes portfolio covering the sensor, transducer, and processor patents ('234, '567, and '890), a reasonable offer of sale would be approximately \$100 million based on the earlier valuations performed. Alternatively, the individual patents could be sold to different companies, but with the caveat that they each would have significantly less value than their valuations due to the fact that they each cover distinct components and may potentially serve to block each of the companies from an unfettered freedom to operate in the embeddable biosensor space.

Enforcement

Many in this field are start-ups and small companies, and lack the financial means necessary to enforce their IP rights or defend their products against competitors and patent trolls should they become involved in costly and time-consuming IP litigation. Thus, demand letters and licensing proposals should be a first option in dealing with an accused infringer. If this tact doesn't work, then litigation must be pursued as a last case resort. Patent litigation has many different components, from claim construction, validity, infringement, damages, to counterclaims and affirmative defenses. [121] In the case of bioinformatics litigation in this newly ushered *Alice*-era, issues of validity will be the area of most risk exposure. Patents may be subject to invalidity based on *Alice* subject matter eligibility standards, not to mention on obviousness, inventorship, enablement, and written description grounds. Demand letters and licensing ultimatums could potentially expose the patent owner to declaratory judgments- a litigation tool for providing a legally binding determination of legal uncertainties in order to

avoid adjudication. The following is an illustrative example of the use of a declaratory judgment, with validity issues as the underpinning.

In one of many examples, Counsyl is counter-suing Myriad, asking the court for a *declaratory judgment* that (1) eight specified Myriad patents are invalid and (2) even if they are valid, Counsyl isn't in infringement. Declaratory judgments are an often employed litigation tool because they allow prospective infringement defendants to ask a court to resolve the uncertainty of infringement, and more importantly, to potentially invalidate the claims altogether. Moreover, the declaratory judgment allows Counsyl to mandate Myriad to counterclaim infringement on Counsyl in this suit, or otherwise be estopped from asserting infringement in any future suit. [122]

Alice-era validity issues may also be remedied through the new post-grant proceedings in the USPTO, as codified by the recently enacted America Invents Act. Notwithstanding the shift from the first-to-invent to the first-to-file system and the substantial expansion of prior art- the salient features of the AIA are pertaining to the remedial procedures for invalidating patents through post-grant proceedings. Under the AIA reforms, the mechanism for invalidating patents has been broadly expanded- including prior art, lack of written description, lack of enablement, and ineligible subject matter. It is adjudicated before the Patent Trial and Appeal Board and is based on motion practice. There are, however, significant limitations. For one thing, it can only be initiated within 9 months of the issuance of the patent or a reissue that broadens the scope of the original claims. Additionally, a challenger is precluded from a Post Grant Review (PGR) if a district court challenge was earlier initiated, and vice versa, precluded from district courts if a PGR was earlier initiated. Finally, the standard for initiating the PGR is that it is 'more likely than not' that one or more of the challenged claims are unpatentable. [123] In the aftermath of the AIA reforms and the sudden rise of bioinformatics patents being issued, the PGR pathway to invalidity grounded in *Alice* should be anticipated.

Another potential concern, especially for smaller bioinformatics firms, is the threat of demand letters and litigation from so-called patent trolls, more specifically, non-practicing entities. The NPE's that are the focus of this analysis are the patent aggregators, such as Acacia and Intellectual ventures (IV), and not the upstream actors, such as universities, individual inventors, etc. The issue is not the secondary markets for patents or even some upstream innovators and intermediaries. This secondary market creates liquidity and alienability of these valuable assets. It fosters innovation, the aggregation of which creates market efficiencies. Using patent monetization markets and VC financing as a metric for the current state of innovation and patent economy, we looked at data from the Robin Feldman's forthcoming UCLA J.L & Tech article, as well as data from the NVCA report, "Patent Demands & Start-up Companies: The View from the Venture Capital Community". This report looks beyond just patent litigation data, but also the patent demands, which include pre-litigation licensing demands, not to mention litigation threats and service of complaints. The report and all of the ensuing scholarship and public commentary by critics and practitioners is overwhelmingly in favor of curbing NPE's and especially the aggregating monetizers (i.e., Intellectual Ventures, Acacia, etc.). There is consensus among these sources that these demand letters have had a negative impact on venture capital financing. Most of the findings are empirical and based on poll data of actual venture capitalists that hold companies that have been subjected to these demand letters. *The vast majority of patent demands against startup companies come from entities that license or litigates patents as their core activity (Specifically, 59% of the venture capitalists and 66% of the startup companies reported that all or most came demands come*

from such entities). [124] One hundred percent of venture capitalists indicate that if a company had an existing patent demand against it, it could potentially be a major deterrent in deciding whether to invest. Roughly half indicate that it would simply be a major deterrent on its face, and the other half indicates that it could be a major deterrent, depending on the circumstances. [125] By some estimates, there has been a \$21 billion loss in VC investments over the past five years due to troll demanding. [126]

Bioinformatic companies, start-up or otherwise, are just as exposed to the troll pandemic. In fact, they may be even more exposed, than companies that do not exploit IT-based platforms, according to Bessen and Meurer, in a 2012 study (Figure 12).

Summary Characteristics of Lawsuits	
Publicly listed defendants Number	
Mean	15.3
Median	5
Percent	
Sole defendant	17
In litigation with 10 or more defendants	32
Software patent	62
Patent Technology Classes (NBER) Percent	
Chemical	1
Computers and communications	75
Drugs and medical	1
Electrical and electronics	12
Mechanical	4
Other	8

Figure 12. Number of defendants by sector subjected to NPE litigation. (Bessen and Meurer, 2012)

With this in mind, while Congress- in typical gridlock fashion- continue to mull over options on how to combat the troll problem, some bioinformatics start-ups have taken measures into their own hands. Case in point, Reflx, a Seattle based wearable and biosensor company, who recently launched their flagship product, Boogio, a shoe sensor. Reflx built a portfolio around Boogio and future products, and instead of waiting to be served a demand letter or complaint from a troll, they decided to form a strategic partnership, not with just any troll- but the market leader of NPE aggregators, Intellectual Ventures (IV). Why would a bioinformatics start-up get into bed with the king of trolls? Because Reflx gave IV equity in the company in exchange for help developing and selling software development licenses, according to Reflx CEO, Jose Torres. [127] In other words, strategic alliances may avoid threats of ex facto licensing, and leverage a start-ups' current portfolio in the secondary markets. The complexity of cloud server applications and software packages will allow us to interface with our physiological data streams in real-time. These systems will usher in a new era of personalized health care delivery, promising efficiencies in outcomes, access, and cost-containment.

However, it all begs serious ethical concerns, namely issues of privacy and encroaching on the public commons.

FDA'S ROLE IN THE 'APP' WORLD

"FDA clearance is an important step on the path towards getting genetic information integrated with routine medical care" - Anne Wojcicki

As mentioned earlier, the future of medicine in the succeeding decades will be an amalgamation of IT-lead personalized health care devices. Hence, the next big question is what type of device will the FDA classify as a personalized healthcare device and how long will it take to pass through FDA regulatory approval process? Also, what is the best strategy for a startup to navigate through this regulatory labyrinth?

One of the foremost aspects to consider is what kind of device the FDA considers to be a personalized medical device. According to the FDA's perspective as mentioned earlier: "Personalized medicine generally involves the use of two medical products – typically, a diagnostic device and a therapeutic product – to improve patient outcomes. [7] Therefore, according to current FDA standards and regulatory schemes, personalized medical devices diverge from class I to class III. Additionally, under existing guidelines, all devices regardless of its class are subject to general controls which includes the following: 1) establishment registration by manufacturers, distributors, repackages, and re-labelers, 2) medical device listing with FDA of devices to be marketed, 2) manufacture devices with GMP (Good Manufacturing Practices), 3) labeling regulations, and 4) MDR (Medical Device Reporting) of adverse events as identified by the user, manufacturer and/or distributor of the medical device. Class I devices are general controls and are commonly exempt from premarket notification 510(k). One example of a class I devices are Band-Aids. Class II devices are special controls which require Premarket Notification 510(k). One example of a class II device is diagnostic equipment. In fact for class II devices includes special labeling requirements, mandatory performance standards (domestic and international), post market surveillance, FDA medical device specific guidance, and pre-market notification by submission, and FDA review of a 510(k) clearance to market submission. Class III devices require Premarket Approval (PMA). One example of a class III device is replacement heart valves. The class III devices have the utmost stringent regulatory controls and are higher risk devices, where all class I general controls and class II special controls apply. Moreover, they are subject to FDA approval based on safety and effectiveness as well as PMA. [128] The class of the personalized health care device is unknown and indefinite under current FDA regulations. One of the first steps a start-up currently should take is to send a Request for Designation Document (RFD) to the Office of Combination Products which will determine the type of product and which the Lead Center of that product will be regulated in. [129] This will inform the start-up on what regulatory path to follow and dictate crucial engineering and design decisions.

Since the FDA regulations are very difficult and may take many years, an alternative opportunity for a start-up is gaining approval in the European Union, which usually takes considerably less effort and time than gaining approval through the FDA in the United States. However, this will only allow the start-up company to start selling the personalized healthcare

devices in Europe while waiting for FDA approval in the United States which might prove to be detrimental for the company's patenting strategy in the United States. This regulatory strategy should only be used if there is a relevant patent presence in the European Union. [130] Even though the Supreme Court upheld the ACA (Affordable Care Act), it left the Medicaid expansion option up to the individual states which could significantly alter the potential customers for the personalized healthcare market.

Reimbursement

One important aspect regarding the personalized medical devices is the ability to sell them to individuals and patients in the United States. The CMS (Centers for Medicare and Medicaid) develops and creates Medicare/Medicaid coverage and payment policies for many healthcare services but is not limited to ambulatory surgical centers, physician offices, hospitals, and nursing facilities. Typically many private insurance companies base their coverage on what the CMS decides to reimburse. Once CMS decides to cover the personalized medical device, the start-up company has access to all the Medicare, Medicaid, and private insurance patients that accept the coverage and reimbursement of CMS. Although, there are numerous steps involved in the CMS process, where initially the company must submit a request after which, the NCD (National Coverage Determination) process is initiated. Within 6 months of the NCD including a 30-day public comment period, a proposed decision memo is released in the public followed by another 30-day public comment period. Lastly, after a sixty day period, a final decision on the coverage is released.

The CMS process is very vital for any start-up specifically in the field of personalized wearable device. A start-up in need of revenue will momentarily benefit from CMS as it has potential access to the patients of Medicare and Medicaid. Also, along with the recent healthcare reform, the coverage provided by CMS becomes even more imperative is because it controls access to Medicaid which could insure another 21.3 million Americans in the next decade. That is another 21.3 million potential customers for the personalized healthcare and wearable market. [131] In fact, there is also legislation at the federal level which includes the ACA that will make it easier to access public data on patients, clinical trials, health insurance, and medical advances in the future. Some of these policy levels include the following: the HHS (Health and Human Services) which are starting to liberate data from agency such as CMS due to the 2009 Open Government Directive, the ACA includes a provision that authorized HHS to release data to promote transparency in the markets and health insurance, the HITECH (Health Information Technology for Economic and Clinical Health) Act authorized about \$40 billion in incentive payments for providers to use EMRs (Electronic Medical Records), with an overall goal of driving adoption to 70 to 90 percent of all providers by 2019. [132] With all these incentives, it provides many opportunities for personalized and wearable health care devices include for EMRs along with data continuing to be released to promote transparency in markets and health insurance.

CAN INTELLECTUAL PROPERTY AND OPEN SOURCE CO-HABITATE?

“Intellectual property is an important legal and cultural issue. Society as a whole has complex issues to face here: private ownership vs. open source, and so on” - Tim Berners-Lee

A patent gives its owner the right to exclude others from making, using and selling the claimed invention, whereas an open source license gives anyone who obtains a license to a particular product or software to use and view the code and modify it for his own purpose without the permission of the author. Samsung's Simband is an open source sensor platform for healthcare and wearable technology. Simband is a first prototype, which can utilize its sensors to measure bioimpedance. Simband's arsenal of sensors generates a mountain of data which requires a robust, purpose-built software engine to make sense of it. [133] SAMI is a cloud-based open software platform which makes more information available, breaks open information silos and gives applications and services access to large amounts of data to provide better insights. [133] Simband along with SAMI are intended to be used by the medical industry both in academia as well as by startups to develop new applications and software for sensor technology. Samsung ambitioned into the development of Simband and SAMI to empower a broader shift of wearables from fitness tracking to health monitoring with the goal of enabling preventive healthcare and wellness. The Simband is equipped with six sensors, but it gives flexibility to developers and innovators to add their own proprietary sensor. The six sensors measure daily steps, heart rate, blood pressure, skin temperature and the production of sweat. Simband's sensors are able to track bodily functions at an impressively detailed level. [134] For example, the optical sensor tracks the blood pressure. It uses LED light to track changes in how the light is absorbed by our blood, which allows it to “detect blood-volume change at a microvascular level.” [134] Another example is the Galvanic skin sensor (GSR), which measures the sweat thus, gauging the stress level of our body. [134] The Simband's sensors sense and display a real-time feed of all the stats being collected. [134] The data collected from Simband can also be traced on the web when connected to wifi. However, the bigger question is how these sensors will evolve, how Samsung's cloud will use the data, and how other researchers and companies will be able to develop tools for Simband. Will the Simband's universal platform be a boon or a curse to the future of wearable technology? Simband technology also gives us perspective in acknowledging the fact of how giant of a knoll wearable health tech still has to ascent.

Tesla Motors CEO, Elon Musk recently announced on the company's blog that it would make its patents open to the public, which would allow the automotive community to use its patents and technology in “good faith”. So what does “good faith” use really mean? Musk failed to publicly clarify its exact definition. Moreover, it does not provide a blanket and unmitigated protection against litigation and lawsuit for potential patent users. So is this Tesla's and Samsung's marketing and PR move? Undeniably. An excellent and first-rate business move? Indubitably. This is evident from Samsung's filing of 4652 patents in 2013, where it ranked number 2 in filing at the United States Patent and Trademark Office (USPTO). [135] Additionally, it could also mean that by opening up the Tesla patents to the general public, Tesla wants more automotive manufactures to invest in electric cars, which would in turn lead

to additional and easily accessible front-end infrastructure for electric cars for example, more electric gas stations thus, solving a giant and forthcoming challenge of global supply chain needed for electric cars to run on roads. So does this make Tesla steer into capitalism with a conscience or is this a simply an exceptional and a unique business deal along with a remarkable and a noteworthy public relations move?

Furthermore, OptiProbe's patent portfolio as suggested above is unquestionably going to bring in significant revenue to the company. So should OptiProbe follow the steps of Tesla and Samsung and lean towards making the patents, devices and platforms open for the public to use? That is the consummate question, which conflicts public's opinion about innovation, novelty, inspiration and creativity. What are the consequences of an open source movement? Is it going to halt innovation and novelty? Only time will tell if the future of wearable technology is the future of smart and shrewd business. Till then, we can embrace cutting edge wearable technology that will help us make smarter and healthier personal decisions.

BIG DATA AND PRIVACY: BIG CHALLENGE OF THE FUTURE

"In digital era, privacy must be a priority. Is it just me, or is secret blanket surveillance obscenely outrageous?" - Al Gore

Big data drives big benefits, from innovative businesses to new ways to treat diseases. [136] The Obama administration in its second term have pushed for a digital government and making health data easily accessible to the public. One of the major tools in the information technology tool box is via the use of APIs. APIs make information more accessible. [137] First, the use of APIs makes it easier to replicate government information across more places than ever before. APIs enable automatic updates of information when content is syndicated on other websites, while reducing actual person hours currently spent manually updating content. [137] Second, APIs make information and data easily available to developers, who can create web and mobile applications that make information increasingly more useful to the public. [137] Creating these automated connection points between the data and external computer systems will ease the data's use and its transfer to outside systems creating true data liquidity to fuel algorithms, support data visualizations, or be used in other tools and services. [138] The government is striding towards a digital government and making information and data more liquid, accessible, manageable and useful, so that the public can use the data in a more meaningful way.

The next big challenge for the government is the privacy issues that ascend because of easy access to big data. The challenges to privacy arise because technologies collect so much data (e.g., from sensors in everything from phones and medical devices to parking lots) and analyze them so efficiently (e.g., through data mining and other kinds of analytics) that it is possible to learn far more than most people had anticipated or can anticipate given continuing progress. [136] Technology by itself cannot protect privacy, and policy intended to protect privacy needs to reflect what is (and is not) technologically feasible. [136] The term "privacy" encompasses not only avoiding observation, or keeping one's personal matters and relationships secret, but

also the ability to share information selectively but not publicly. [136] The promise of big-data collection and analysis is that the derived data can be used for purposes that benefit both individuals and society. [136]

Big data can provide enormous benefits in many areas of technology from surveillance to advertising to medicine, but on the flip side can also be accompanied with several privacy challenges. With an unprecedented growth in the field of personalized medicine, healthcare and wearable technology, there is an exponential increase in the volume of data generated. Additionally, privacy concerns regarding patient's health, histories and records could also be jeopardized. The following are a few examples in the field of personalized medicine and healthcare via mobile devices, where privacy and concealment of data is an emerging concern.

- **Personalized Medicine**

Not all patients who have a particular disease are alike, nor do they respond identically to treatment. [136] Researchers will soon be able to draw on millions of health records (including analog data such as scans in addition to digital data), vast amounts of genomic information, extensive data on successful and unsuccessful clinical trials, hospital records, and so forth. [136] In some cases they will be able to discern that among the diverse manifestations of the disease, a subset of the patients have a collection of traits that together form a variant that responds to a particular treatment regime. [136]

Since the result of the analysis could lead to better outcomes for particular patients, it is desirable to identify those individuals in the cohort, contact them, treat their disease in a novel way, and use their experiences in advancing the research. [136] Their data may have been gathered only anonymously, however, or it may have been de-identified. [136]

Solutions may be provided by specific new technologies for the protection of database privacy. [136] These may create a protected query mechanism so individuals can find out whether they are in the cohort, or provide an alert mechanism based on the cohort characteristics so that, when a medical professional sees a patient in the cohort, a notice is generated. [136]

- **Wearable Technology:**

Many baby boomers wonder how they might detect Alzheimer's disease in themselves. [136] What would be better to observe their behavior than the mobile device that connects them to a personal assistant in the cloud (e.g., Siri or OK Google), helps them navigate, reminds them what words mean, remembers to do things, recalls conversations, measures gait, and otherwise is in a position to detect gradual declines on traditional and novel medical indicators that might be imperceptible even to their spouses? [136]

At the same time, any leak of such information would be a damaging betrayal of trust. What are individuals' protections against such risks? [136] Can the inferred information about individuals' health be sold, without additional consent, to third parties (e.g., pharmaceutical companies)? [136] What if this is a stated condition of use of the app? [136] Should information go to individuals' personal physicians with their initial consent but not a subsequent confirmation? [136]

HIPAA and the Age of Big Data: Old Laws New Problems

As mentioned above, Big Data has tremendous potential in the medical and healthcare industry, but is potentially perilous with respect to the privacy of a patient. By amassing and analyzing massive quantities of digital information from multiple sources, including an emerging class of wearable devices and smartphone apps, medical professionals will be well equipped to solve major health problems and warn people of emerging threats like the Ebola virus. [139] Furthermore, since the beginning of the Obama administration and the turn of the decade, the federal government has used its enormous power to push the medical and healthcare industry to synchronize care, embrace new technologies and cut costs, all in an effort to transition towards a more cost-effective model of healthcare. But representatives from a broad swath of the health economy – providers, insurers, and health information technology professionals – say the same resources haven't been leveraged to update existing regulations or inform the healthcare community about how old rules apply in the new world. They worry that they're increasingly navigating a regulatory minefield with an out-of-date map. [139] One of the most imperative apprehension of these professionals is the Health Insurance Portability and Accountability Act (HIPAA) law which was passed in 1996 by then President Bill Clinton that oversees the transfer of health information data under the threat of fines and legal penalties for data breaches and unsanctioned practices. Amazon's Paul Milsener, pointed out to Congress that outdated aspects of the law are impeding his company's move into the health information technology sector and that Congress needs to work with the Department of Health and Human Services to modernize the implementation of HIPAA so that healthcare providers can readily employ the benefits of cloud computing without a compromise of the strong protections HIPAA now affords health information in an effort to accelerate the delivery of new biomedical treatments and cures. [139] With the advances in technology, parts of this law has become obsolete. There is, additionally, the concern that many actors in the wearable space would not be considered covered-entities under the extant HIPAA laws, therefore being shielded of any breaches.

HIPAA is also triggering dyspepsia among the medical community. The law was passed when the doctors were not likely to be carrying around thousands of patient files in the palm of their hands. The law still levies penalties based on the volume of data that's been compromised in a security breach. [139]

The increase in wearable technology in the near future also poses a significant challenge between Tele-health and HIPAA laws. Consultations via FaceTime, videoconferences and Skype are not via a secure network and the breach of information would jeopardize the physicians practice. This causes reluctance among doctors to adapt to novel technologies out of apprehension over potential penalties stemming from the unintentional misuse of digital platforms.

The next big question in the era of cyber and digital world is who owns the big data? As more and more data is generated, storage of this data is amplified. When we talk of about data ownership, we refer to the storage of the generated data. Thus, 'my data' have multiple owners, and the number of owners increases with each share. [140] This arises another question of who possesses the right to use the information and data which is collected that truly does not belong to one's self. This is an issue that transcends borders of commerce, ethics, and morals, leading to privacy issues and protection of privacy. [140]

The fourth Amendment states, “The right of the people to be secure in their persons, houses, papers, and effects...” puts only the physical body in the rhetorically more prominent position, where individuals’ privacy is physically protected in the confines and boundaries of their house. The prevailing interpretation of the Fourth Amendment is inadequate for the present-day digital world. We, along with the “papers and effects” contemplated by the Fourth Amendment, live increasingly in cyberspace, where the physical boundary of the home has little relevance. [136] Hence, it becomes extremely imperative that law makers as well as policy and decision makers at the federal and state level address these issues without delay rather than address them when harm ensues.

Privacy has a noteworthy anthropological value. The advances of technology both threatens personal privacy and provide opportunities to enhance its protection. [136] The challenge for the U.S. Government and the larger community, both within this country and globally, is to understand what the nature of privacy is in the modern world and to find those technological, educational, and policy avenues that will preserve and protect it. [136] Furthermore, governments globally will need to play a more active role to protect citizens’ privacy rights, in light of the evolving and digital world we live in today. [140] Notwithstanding, the break-neck pace of development in the wearable health sector promises to usher in a healthcare era in which the inalienable right to personally tailored healthcare can be achieved by anyone, anytime, and anyplace. Innovations will be inextricably intertwined on the branches and nodes of the ever-growing tree of healthcare technology. In particular, the wearable healthcare sector will sprout strategic assets that will, undoubtedly, require a crafted patent strategy and roadmap. Strategic guideposts and a patent roadmap will be necessary to circumvent the myriad of legal pitfalls in order to properly leverage the low-hanging fruit of wearable biosensor innovations.

ACKNOWLEDGMENTS

We are exceptionally grateful to Dr. Yanjiao Zhou, an instructor at Washington University School of Medicine, St. Louis, for her valuable insight and critical reading of the manuscript. She was one of the leaders in analyzing the Human Microbiome Project metagenomics data studies and is trained in the fields of bioinformatics, microbiology and immunology. We are exceptionally grateful and appreciative to Dr. Hemraj Juwarker, a research fellow at Duke University Medical Center, where he is involved in developing novel therapeutics for chronic inflammation and thrombosis. We are also grateful to Michael Andraos and Carina Kraatz, both associates at Fernandez & Associates, LLP, for their valuable insight and discussions during the course of our research and for their critical reading and analysis of the manuscript. We are also thankful to Dennis Fernandez, managing partner at Fernandez & Associates, LLP, for giving us the opportunity to write this article and for his insightful and judicious suggestions.

ABSTRACT

Marfan syndrome is a heritable disorder of connective tissue that is transmitted as an autosomal dominant trait and is characterized by the mutation in the fibrillin 1 gene (FBN1). At present, the diagnosis of Marfan syndrome, based on Ghent criteria, considers both clinical evaluation (in which it is possible to observe alterations in eye, osteoarticular apparatus and cardiovascular system) and genetic evaluation (that reveals a FBN1 gene mutation). Moreover, we take into account the presence of affected relatives suffering of the same syndrome. The diagnosis of Marfan syndrome is often complex because of the evolution of the phenotype with age (Lipscomb, 1997) and because of the inter-individual variation in the clinical presentation even among the affected family members. According to a recent review (Baeza-Velasco, 2014), Marfan syndrome is often associated with a range of psychiatric problems like anxiety disorders, depressive disorders, schizophrenia, neurodevelopmental disorders (autism spectrum disorder and attention deficit/hyperactivity disorder) and eating disorders. We report a 16 years old female patient (MF) (kg 43, H 165 cm, BMI 16.9) who came to our outpatient service for a selective feeding successively diagnosed as Avoidant/Restrictive Food Intake Disorder (ARFID; DSM 5). “Selective feeding” refers to children who restrict the ingestion of food to a limited number of “favourite” foods, typically five or six different foods (Lask and Bryant-Waugh, 2000). ML., indeed, eats only pasta, sweets and a few other foods. Beyond the altered feeding behaviour, she was diagnosed with a mild intellectual disability (IQ=57; VIQ=61; PIQ=62) and reduced adaptive levels in the socialization and communication domains of the Vineland Adaptive Behavior Scales (VABS). This patient presented ligamentous laxity, long-limbed body habitus suggestive for Marfan syndrome. Therefore, she was addressed to the cardiologist: the echocardiographic evaluation showed mild

dilatation of aortic root, with rectilinear sinotubular junction and enlarged ascending aorta (z score=2). Z-scores of the aortic root at the level of the aortic annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta measured from the parasternal long axis in diastole using leading-edge-to-leading-edge technique. The eye examination was normal. Sanger sequencing of the FBN1 gene identified the c.7501G>A (p.Val250Ile) variant/mutation. The missense mutation/variant is not reported in UMD, Ensemble, Exome variant server and dbSNP. The SIFT, PoliPhen2, Mutation Tester (software tool) for predicting damaging of missense mutations and variants gave the following results: PoliPhen2: benign; Mutation Tester: disease causing, SIFT: tolerant. Her mother carries the same mutation. ML. is affected by ARFID, (mild) intellectual disability and adaptive disorders often associated with Marfan syndrome, confirming and extending the results obtained in the review previously described (Baeza-Velasco, 2014). Moreover, we underline the importance in multidisciplinary diagnosis and care (also) in these cases.

INTRODUCTION

1. Marfan Syndrome

Heritable disorders of connective tissue consist of a group of genetic diseases that affect the proteins of the connective tissue matrix such as collagen, elastin, fibrillin and tenascin (Baeza-Velasco, 2014).

Marfan syndrome is a heritable disorder of connective tissue characterized by mutations in fibrillin 1 gene (FBN1) (Dietz, 1991). This protein is present in the ocular, skeletal and cardiovascular systems. At present, the diagnosis of Marfan syndrome, based on Ghent nosological criteria, (Loeys, 2010), considers both clinical evaluation (in which it is possible to observe alterations in eye, osteoarticular apparatus and cardiovascular system) and genetic evaluation (that reveals a FBN1 gene mutation). Moreover, we take into account the presence of affected relatives suffering of the same syndrome transmitted as an autosomal dominant trait. The diagnosis of Marfan syndrome is often complex because of the evolution of the phenotype with age (Lipscomb, 1997) and because of the inter-individual variation in the clinical presentation even among the affected family members. As shown in a recent review (Willis, 2009), the Authors showed that early diagnosis is very important: the patients that received the Marfan syndrome diagnosis before 18 years of age had less heart surgery (33% vs 59%) and have a better outcome.

2. Association between Marfan Syndrome and Psychiatric Disorders

Kaplan and Katz (1992) were the first to underline the possible coexistence of eating disorders and connective tissue diseases. A recent review (Baeza-Velasco, 2014) confirmed the association between heritable disorders of connective tissue and a wide range of psychiatric problems like anxiety disorders, depressive disorders, schizophrenia, neurodevelopmental disorders (autism spectrum disorder, attention deficit/hyperactivity disorder and developmental coordination disorder), eating disorders and personality disorders (anxious obsessive-compulsive personality disorder). Goh and colleagues (2013) affirm that joint hypermobility, peculiar feature of heritable disorders of connective tissue, is “a possible indicator of familial

disorders of connective tissue elasticity, which potentially plays a causal role in the development of the eating disorder” (p.1). Recent studies (Miles, 2007) dealt with the association between anorexia nervosa and specific connective tissue diseases, like Ehlers-Danlos syndrome.

Behaviour problems related to food have been reported in some genetic neurodevelopmental syndromes, particularly in Prader-Willi syndrome, characterized, in fact, by obesity and hyperphagia. Only recently eating disorders have not been specifically investigated in others genetic syndromes, such as Angelman syndrome, the “sister imprinted disorder” of Prader-Willi syndrome, Cornelia de Lange, Fragile X, and 1p36 deletion syndrome (Welham, 2014).

As regards the neurodevelopmental disorders, instead, Shetreat-Klein and colleagues (2014) observed that children with Autism Spectrum Disorder (ASD) had significantly greater joint mobility than their matched normally developing peers. Moreover, cases have been described in which a ASD (precisely, Asperger syndrome) coexisted with lifelong ligamentous laxity and muscular incoordination suggesting a “Marfan-like” disorder of connective tissue (Tantam, 1990).

3. Selective Feeding

Lask and Bryant-Waugh (2000) provided an important contribution to the classification of eating disorders in developmental age. They suggested a number of guidelines, known as Great Ormond Street Criteria (GOS), directed at identifying eating disorders for those aged under 14 years. The GOS include six different clinical conditions: anorexia nervosa, bulimia nervosa, emotional disturbance of food refusal, selective feeding, functional dysphagia and pervasive refusal.

The definition of “selective feeding” refers to children who restrict the ingestion of food to a limited number of “favourite” foods, typically five or six different foods. The diet is rich in carbohydrates, especially bread, chips and cookies. Even the drinks could be selected, they are usually milk or milk-based beverages. The attempt to increase the number of food or beverages meets extreme resistance.

Sometimes, selective feeding is associated with some psychiatric disorders, such as autism spectrum disorders (Bandini, 2010) or complex patterns of behaviour, such as a tendency not to change their habits and the incapability to tolerate new situations.

According to the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; APA, 2013), a disorder similar to that previously described, is diagnosed as a disorder avoidant / restrictive of food intake (ARFID), characterized by avoidance or restriction in food intake (Criterion A), associated with at least one of the following: relevant weight loss, significant functional deficit, dependence it from parenteral or from oral nutritional supplements, marked interference with psychosocial functioning. This disorder does not include a non-availability of food or a cultural practice (Criterion B).

Also, it is not better explained by an excessive concern about weight and shape of own body (Criterion C) or concomitant medical factors or mental disorder (Criterion D).

4. L.'s Clinical Case

At the age of about 16 years, L. came to our clinical attention because of selective feeding. The patient was used to eat only pasta, sweets and a few other foods for more than two years. Her height was 165 cm and weight 43 kg (BMI = 16.9) thus being underweight. Individuals with selective feeding, in fact, could have a low, normal or high body weight, (Lask and Bryant-Waugh, 2000). According to her medical history, there was a mild perinatal distress after pregnancy complicated by threatened abortion. Subsequently, the patient was bottle-fed with a difficult weaning because of the refusal of solid foods and the preferential intake of milk until about 6 years of age. Furthermore, there was a delay in sphincter control (daytime age of 4 and a half years, night at the age of about 6 years), in motor (independent walking after 16 months), and in language development (first words at about 3 years) and poor communicative intentionality. Moreover, there were emotional-behavioural problems characterized by poor socialization, tendency to play alone, narrow field of interest, motor restlessness, poor compliance and easy distractibility to external stimuli. For the developmental delay at the age of 4, L. was admitted to hospital and the presence of any congenital metabolic diseases was excluded. At the age of 6 years, the Wechsler Preschool and Primary Scale of Intelligence (WIPPSI) allowed the detection of a borderline cognitive level (IQT = 76; IQv = 76; IQP = 81). At the age of 9 years after loss of consciousness episodes in situations of emotional stress (venipunctures for hematochemical test), whereas the an electroencephalogram was normal echocardiogram detected mitral valve prolapse. As a consequence of the persistent emotional-behavioural problems previously described and due to difficulties at school, for which L. was followed by a special education teacher from the third year of nursery school, a clinical and neuropsychological assessment was performed. The clinical neurological examination, at the age of about 12 years, revealed dysmorphic features (mild prominence of the frontal bossing (CC: 55.2 cm, 90-97%), dysmorphic face, pectus excavatum, generalized muscular hypotonia, hypomobile and stereotyped facial expressions, bilaterally claw- feet). In the same year, the Wechsler Intelligence Scale for Children- Revised (WISC-R) detected the presence of mild mental retardation (IQ = 55), with a slightly disharmonious profile between verbal (verbal IQ = of 52) and non-verbal skills (performance IQ = of 65) in favour of the latter. Moreover, autistic traits with a greater endangerment in reciprocal social interaction and communication were present. In particular, the Autism Diagnostic Observation Schedule (ADOS module 3) found that L. minimally uses gestures, facial expression and look for social purposes. Therefore, at the age of about 12 years, there was the diagnosis of "mild mental retardation and autism spectrum disorder (generalized disorder not otherwise specified) in patient with dysmorphic features and minor neurological signs". Two years later, at the age of about 14 years, the clinical and neuropsychological reevaluation confirmed the diagnosis of intellectual disability (IQ = 46; VIQ = 48; PIQ = 56). As for the features of social interaction and communication skills, while pointing out an improvement, the examinations confirmed the previous diagnosis of Pervasive developmental disorder not otherwise specified. At present, in order to investigate the problems of L.'s behaviour and social sphere, psychological interviews were conducted and tests were administered designed to further delineate the cognitive profile and to assess the adaptive behaviour of the patient. The Coloured Progressive Matrices (CPM) detected the presence of the analogical-deductive reasoning ability and of abstraction ability below the norm; the evaluation through Figure of Rey has documented both a visual-spatial organization and a recovery mnemonic ability below the norm, and the administration of the Token test has revealed

an ability of seriation and discrimination below the norm. In addition, the assessment by Wechsler Adult Intelligence Scales-Revised (WAIS-R) showed the presence of mild Intellectual Disability (IQ = 57; VIQ = 61; PIQ = 62). Therefore, there is no clear discrepancy between scores for verbal subtests and those of performance. The firsts showed deficit in the quality of the relationships that the subject has abstracted from her environment, in the ability to use abstract concepts and in learning skills. Instead, from performance tests shortcomings in the planning of sequences and causal events, in the organization of perception and in motor coordination emerged. Scores of different items are shown in Table 1.

As regards the adaptive behaviour, the Vineland Adaptive Behavior Scales (VABS), compiled thanks to the information provided by the mother, found that L. has reached a level of development lower than that the expected for normally developed peers of the same chronological age in the investigated areas (daily skills and socialization). The patient, in fact, knows the value of coins and notes but needs supervision and assistance in the use of money and in savings management. It emerges lack of autonomy in transfers. There are also difficulties in the area of socialization. L., in fact, has not built deep and satisfying personal relationships outside the family. From the comparison with subjects of the same intellectual disability, however, the area most affected appears to be only the one linked to the daily abilities. Scores of different items are shown in Table 2.

The evaluation by Rating Scale behaviour (Aman-Singh) was possible by the information provided by the patient's mother and it has documented the presence of disorders, in particular a tendency to lethargy and a presence of inappropriate language with a tendency to coprolalia. In addition, the score (17/40) from the compilation, by the mother of L., of the Social Communication Questionnaire (QSC), suggested the presence of a disorder in the autism spectrum.

However, as regards the assessment of symptoms and food related issues such as body image (Vocks, 2007) and dissatisfaction with their body (Stice, 2002), at the administration of the Eating Attitudes Test (EAT) the presence of altered food attitude did not emerge; the evaluation by Body Attitudes Questionnaire (BAQ) has not detected an altered perception of the body image while the administration of the Eating Disorder Inventory-2 (EDI-2) showed the presence of dissatisfaction with her own body.

These results confirm the fundamental difference between the patients with anorexia nervosa or bulimia nervosa and those with selective feeding, which is the absence in the latter of morbid concerns to the weight and shape of their body and of an altered body image (Lask and Bryant-Waugh, 2000). L. has, therefore, a mild intellectual disability, analogical-deductive reasoning skills and of abstraction, seriation and discrimination skills, visuospatial organization skills and of mnemonic recovery below the norm, behavioural disorders, autism spectrum disorder and selective feeding. Due to the Marfan like phenotype specific investigations were carried out. The echocardiographic evaluation showed mild dilatation of aortic root, with rectilinear sinotubular junction and enlarged ascending aorta (z score=2). Z-scores of the aortic root at the level of the aortic annulus, sinuses of Valsalva, sinotubular junction, and ascending aorta measured from the parasternal long axis in the diastolic phase using leading-edge-to-leading-edge technique. The eye examination was normal. The molecular genetics detected the presence of a mutation of fibrillins 1, a feature of Marfan syndrome, namely: exon 60: c.7501G> A (p.Val2501Ile).

The clinical and genetic study was extended to the family members of the patient. The same mutation was present in the mother. Our patient at age 18 years, finally received the diagnosis of Marfan syndrome associated with mild intellectual disabilities, analogical-deductive reasoning skills and abstraction, seriation and discrimination skills, organization

skills and visuospatial mnestic recovery below the standard, behavior disorders, autism spectrum disorder and selective feeding.

CONCLUSION

A recent review (Baeza-Velasco, 2014) revealed an association between heritable disorder of connective tissue, like Marfan syndrome, and a wide range of psychiatric disorders. Examples of these disorders are neurodevelopmental disorders (particularly autism spectrum disorder and developmental coordination disorder) and eating disorders.

During infancy our patient presented a developmental delay (onset of independent walking after 16 months) associated with clumsiness and Autism Spectrum Disorder (ASD). There is an association between joint hypermobility and motor delay in children (Baeza-Velasco, 2014). Hypotonia is a feature frequently seen in children with Autism Spectrum Disorder (Baeza-Velasco, 2014); a link between ASD and connective tissue disorders has been suggested. The latest version of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; APA, 2013) stressed functional difficulties in Developmental Coordination Disorder (DCD) and "clumsy" children with joint hypermobility. A selective eating disorder was also described since the first years of life. This is frequently associated with an autism spectrum disorder.

Behaviour problems related to food have been described in some genetic syndromes of neurodevelopment, particularly in Prader-Willi syndrome, characterized, in fact, by obesity and hyperphagia. As of today, eating disorders have not been specifically investigated in other genetic syndromes, such as: Angelman syndrome, the "sister imprinted disorder" of Prader-Willi syndrome, Cornelia de Lange, Fragile X, and 1p36 deletion syndrome (Welham, 2014). The clinical case of L. therefore, allows confirming and extending the results in the literature regarding the association between Marfan syndrome and psychiatric disorders. L. is affected by mild intellectual disabilities, analogical-deductive reasoning skills and abstraction, seriation and discrimination skills, organization skills and visuospatial mnestic recovery below the standard, behaviour disorders, autism spectrum disorder in a subject with selective feeding and Marfan syndrome.

In addition, the clinical case of L., highlights the need for a multidisciplinary approach to diagnosis, as emphasized by the new criteria of Ghent and by the consequent guidelines (Loeys, 2010). The importance of a multidisciplinary treatment depends on the great number of problems associated with Marfan syndrome and the possible presence of comorbid disorders, like in L. clinical case. We hope that further studies will increase knowledge on genetic syndromes and their possible association with psychiatric disorders, noting, if it possible, the causal link between the different problems.

**OPTIMIZING OIL PRODUCTION IN *B. NAPUS* BY
GENE STACKING: TRANSGENIC CO-EXPRESSION
OF *DGAT1* AND PARTIALLY-SUPPRESSED *MTPDCK*
CUMULATIVELY ENHANCE SEED LIPID DEPOSITION**

Elizabeth-France Marillia, Tammy Francis and David C. Taylor*

National Research Council of Canada, Saskatoon,

ABSTRACT

We have previously shown that introduction of single genes encoding diacylglycerol acyltransferases (*DGAT1s*) or partially-silenced mitochondrial pyruvate dehydrogenase kinase (*mtPDCK*), each had the capacity to enhance seed oil content in *Arabidopsis*. In the current study, we report the cumulative effects of expressing a two-gene stack: a site-directed mutagenized *DGAT1* from *Tropaeolum majus* (Tm*DGAT1* Ser¹⁹⁷-to-Ala¹⁹⁷) and an anti-sense *mtPDCK* from *B. napus* (*A/S mtPDCK*) introduced into *B. napus* cultivar DH12075 to alter seed oil content. Compared to plasmid-only controls, the best lines of the two-gene construct showed, on average, a 23.6% proportional increase (11.6% net increase as % of DW) in oil content which is near-additive to the best results obtained in transgenic experiments with the single genes. These findings demonstrate the utility of stacking two specific transgenes controlling the key steps in two very different metabolic streams-mitochondrial carbon flux (*mtPDCK*; “push”) and triacylglycerol assembly via the Kennedy pathway (*DGAT1*; “pull”), to bring about significant increases in oil content in *B. napus*. This approach holds promise for similar use in other oilseed crops.

Keywords: Seed oil content, triacylglycerol synthesis, carbon flux, diacylglycerol acyltransferase, mitochondrial pyruvate dehydrogenase kinase, gene stacking

INTRODUCTION

The global demand for vegetable oils for food, bio-diesel and bio-products is increasing at a rapid pace. It is estimated that a 75% increase in canola oil production will be required to meet the growing markets projected for 2020 (Weselake et al., 2009). In addition to increasing the land area devoted to the canola crop, an improvement in oil content is another approach to enhance oil production using current acreage. Plant breeders have applied a quantitative trait loci (QTL) approach to define the link between embryo and maternal genetics, cytoplasmic effects and genotype-by-environment interactions as partial determinants of seed oil content. Beyond these studies the use of genetic engineering, more specifically, the over-expression or suppression of genes encoding enzymes involved in the channeling of carbon into seed oil, has shown utility for significantly improving seed triacylglycerol (TAG) content. Salient to the current study, it has been shown that over-expression of genes encoding acyltransferases of the Kennedy pathway and repressing those controlling respiratory carbon flux can be used to alter the accumulation of oil in the developing seed (Taylor et al, 2011).

The interactions of pathways involved in fatty acid biosynthesis and seed oil (triacylglycerol, TAG) bioassembly, and the physiological and developmental regulatory factors implicated in seed oil production, have been reviewed recently by Bates et al., (2013) and Baud and Lepiniec (2010), respectively, and the reader is referred to these excellent treatises. While significantly more complex, for the purposes of this paper, we will focus on TAG synthesis in its most basic form, as catalyzed by the membrane-bound enzymes of the Kennedy pathway (Kennedy, 1961) that operate in the endoplasmic reticulum (Stymne and Stobart, 1987). The process begins with *sn*-glycerol-3-phosphate (G-3-P) undergoing two acylations catalyzed by the acyltransferases glycerol-3-phosphate acyltransferase (GPAT; EC 2.3.1.15) and *lyso*-phosphatidic acid acyltransferase (LPAAT; EC 2.3.1.51). The final acylation of *sn*-1,2-DAG by diacylglycerol acyltransferase (DGAT; EC 3.2.1.20) to produce TAG, occurs after removal of the phosphate group from the *sn*-3 position of the glycerol backbone by phosphatidic acid phosphatase (PAPase; EC 3.1.3.4).

In the Kennedy pathway, DGAT is the only enzyme that is exclusively committed to TAG biosynthesis using acyl-CoA as its acyl donor. It has been suggested that DGAT may be one of the rate-limiting steps in plant storage lipid accumulation (Ichihara et al., 1988; Perry and Harwood, 1993a & b; Perry et al., 1999; Jako et al., 2001; Weselake, 2005; Lung and Weselake, 2006), and thus a potential target in the genetic modification of plant lipid biosynthesis in oilseeds for economic benefit (Figure 1).

Accordingly, transgenic manipulation of *DGAT1* expression has resulted in enhancement of oil accumulation in the developing embryo during seed development, suggesting that activity of the corresponding indigenous enzyme is indeed, in part, rate-limiting for oil synthesis. Nowhere is this rate-limitation evidence more clear than in our studies of the *Arabidopsis* mutant AS11 having a lesion in *DGAT1* (an exon 2 repeat), which results in a knockout of DGAT activity and greatly reduced oil content. Transformation of AS11 with the wild type *A. thaliana* *DGAT1* was shown to rescue the low oil phenotype of the mutant (Zou et al., 1999; Jako et al., 2001; Xu et al., 2008). Subsequently, in our lab, lines with enhanced oil content were created by seed-specific over-expression of an *Arabidopsis* *DGAT1* in wild type *Arabidopsis* (Jako et al., 2001) and in *B. napus* cv Quantum (Taylor et al, 2009), suggesting that enhancement of DGAT1 activity may provide the metabolic “pull” needed to more

efficiently channel acyl moieties into TAGs and up-regulate the efficiency of the Kennedy pathway in general.

Figure 1. Increasing oil content by over-expression of DGAT1. Diagram showing the intersecting biochemical steps for glycerolipid biosynthesis in oilseed cotyledons and key enzymes (circled): GPAT, glycerol-3-phosphate acyltransferase (EC 2.3.1.15); LPAAT, lyso-phosphatidic acid acyltransferase (EC 2.3.1.51); PAPase, phosphatidic acid phosphatase (EC 3.1.3.4) and DGAT1, diacylglycerol acyltransferase 1 (EC 3.2.1.20) are the enzymes of the traditional Kennedy pathway (Kennedy, 1961). R1-Ac, R2-Ac and R3-Ac are fatty acyl-CoA donors for GPAT, LPAAT and DGAT1, for esterification at the respective *sn*-1, *sn*-2 and *sn*-3 positions on the glycerol backbone. DAG, *sn*-1, 2-diacylglycerol is the acyl acceptor for DGAT1 (as well as PDAT and DGAT2). The relative contributions of DGAT1 (the focus of this study, shown in red), diacylglycerol acyltransferase 2 (DGAT2), diacylglycerol transacylase (DGTA) and phospholipid:diacylglycerol acyltransferase (PDAT, which donates an R2-Ac from phosphatidylcholine to the *sn*-3 position of DAG) in conversion of DAG to TAG, probably vary among crop species. In canola, evidence suggests that DGAT1 is the predominant contributor. LPCAT is acyl-CoA: lyso-phosphatidylcholine acyltransferase (EC 2.3.1.23) which catalyzes the acyl-CoA-dependent exchange of oleoyl moieties (R2-Ac) at the *sn*-2 position of PC with the polyunsaturated *sn*-2 fatty acids 18:2 and 18:3, (produced by the action of FAD2 and FAD3 on phosphatidylcholine respectively; not shown). CPTase (EC 2.7.8.2) is diacylglycerol-choline phosphotransferase and PDCT is phosphatidylcholine diacylglycerol cholinephosphotransferase. These two enzymes mediate interconversions between phosphatidylcholine (PC) and diacylglycerol (DAG), thus enriching PC-modified fatty acids in the DAG pool prior to forming TAG. Often the result is polyunsaturated fatty acid or hydroxyl/epoxy fatty acid enrichment in the DAG and ultimately, the TAG pool. Thus, plants can use two main pathways to produce diacylglycerol (DAG), the immediate precursor molecule to TAG: (1) *de novo* DAG synthesis, and (2) conversion of the membrane lipid phosphatidylcholine (PC) to DAG (Bates and Browse, 2012). PLA1 and PLA2 are phospholipase A1 and phospholipase A2, respectively. Additional abbreviations: G3P, *sn*-glycerol-3-phosphate; LPA, lysophosphatidic acid; LPC, lysophosphatidylcholine; PA, phosphatidic acid; PC, phosphatidylcholine; TAG, triacylglycerol, containing *sn*-1 R1, *sn*-2 R2 and *sn*-3 R3 acyl moieties. For a more detailed treatment the reader is referred to Weselake (2005) and Bates et al., (2013).

In the developing embryo, energy is largely generated during dark respiration by conversion of photosynthate to pyruvate (via glycolysis) which is imported into the mitochondrion, where it is converted to acetyl-CoA which, in turn, feeds into the TCA cycle, producing ATP and reducing equivalents. These are required for various anabolic reactions, including those which contribute to the synthesis and accumulation of seed oil. The key link

between glycolytic and respiratory carbon flux, the conversion of pyruvate to acetyl-CoA, is catalyzed by the mitochondrial pyruvate dehydrogenase (mtPDH) complex. The enzyme mitochondrial pyruvate dehydrogenase kinase (mtPDHK, EC 2.7.1.99), is the negative regulator of mitochondrial pyruvate dehydrogenase (mtPDH, EC 1.2.4.1) (Rubin and Randall, 1977; Luethy et al., 1996; Zou et al., 1999; Buchanan et al., 2000; Marillia et al., 2003; Tovar-Méndez et al., 2003). We found that constitutive partial suppression of *Arabidopsis* mtPDHK via anti-sense (A/S mtPDCK) resulted in transgenic *Arabidopsis* lines having greater respiratory CO₂ release, earlier floral initiation, earlier maturity, enhanced seed oil accumulation and increased harvest index. When the suppression was directed in a seed-specific manner, the effect was primarily at the developing embryo/seed level and improved oil content was the predominant result (Zou et al., 1999a; Marillia, et al., 2003; Weraduwaage, 2013; Dahal et al., 2014) (Figure 2). This suggests that the A/S mtPDHK transgenics have a greater sink strength and that the anabolic properties of dark respiration can be harnessed to more efficiently divert carbon (“push”) to pathways involved in seed oil deposition.

Given these findings, we were interested in comparing results of seed-specific single gene expression of *DGAT1* or A/S *mtPDCK* to those observed upon co-expression of both, to assess whether the latter approach delivers cumulative improvements in *B. napus* oil content.

MATERIALS AND METHODS

Plant Material and Target Genes

All two-gene transformations in this study were performed in the host *B. napus* cultivar DH12075 (kindly provided by Agriculture and Agri-Food Canada, Saskatoon, SK). Single-gene transformation studies were performed in *B. napus* or *Arabidopsis* host cultivars as delineated in Table 1.

After transformation and regeneration, all experimental *B. napus* transgenic and control lines were propagated in the greenhouse at the Kristjanson Biotechnology Complex greenhouses, Saskatoon, under natural light conditions supplemented with high-pressure sodium lamps with a 16 h photoperiod (16 h of light and 8 h of darkness) at 22°C and a relative humidity of 25 to 30%. All *Arabidopsis* plants were grown in a growth chamber at 22°C with photoperiod of 16 h light (120 $\mu\text{E}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) and 8 h darkness.

The *Arabidopsis thaliana* *DGAT1* (GenBank Accession No. AJ238008) was cloned and characterized as described by Zou et al. (1999b) and Jako et al. (2001). The *Tropaeolum majus* *DGAT1* was cloned from an EST collection (GenBank Accession No. AY084052) as described by Xu et al. (2008) and the synthesis and characterization of the enzyme after site-directed mutagenesis (SDM) of amino acid residue S¹⁹⁷ to A¹⁹⁷, was also detailed therein. The *A. thaliana* mitochondrial *PDCK* (ATCC No. 209562; reported in US Patent No 6,500,670 B1) was cloned and expressed in an anti-sense configuration in *A. thaliana* as described previously Zou et al., 1999a and Marillia et al., 2003). The *B. napus* mtPDCK homolog was cloned and its sequence reported as presented in US Patent No US 7214859 B2 (Marillia et al., 1999).

Bolded data are reported here for the first time.

Production of Transgenic Lines

A. Thaliana DGAT1 Lines

The cloned full-length *A. thaliana DGAT1* cDNA (Gen-Bank No. AJ238008; Zou et al. 1999b) was used as a template for PCR amplification with the primers *Xba*I Forward -5'CTA GTC TAG AAT GGC GAT TTT GGA 3' and *Xho*I Reverse 5'GCG CTC GAG TTT CAT GAC ATC GA 3' to provide new restriction sites at each end of the sequence. The PCR amplification program was as follows: 94 °C for 1 min; 30 cycles of 94 °C for 30 s, 55 °C for 30 s, 72 °C for 1 min; and 72 °C for 5 min. The PCR product was then ligated into the pCR-2.1 vector (Invitrogen Canada, Burlington, ON). The plant transformation vector pSE129A (ATCC 97910; Covello et al., 1997) was prepared from pRD400 (Datla et al., 1992) by introducing a *Hind*III/*Xba*I fragment containing the *B. napus* napin promoter (Josefsson et al., 1987) and a *Kpn*I/*Eco*RI fragment containing the *Agrobacterium* NOS terminator (Bevan, 1983). The 1.6 kb *DGAT1* cDNA fragment was excised from the pCR-2.1 vector by an *Xba*I/*Kpn*I digestion and ligated into the corresponding sites of the pSE129A vector, in the sense orientation. The resulting plasmid was designated napin:*DGAT1*. The construct integrity was confirmed by sequencing. Electro-competent *Agrobacterium tumefaciens* cells, strain GV3101 containing helper plasmid pMP90 (Koncz and Schell, 1986) were prepared, frozen in liquid N₂ and stored at -80 °C as described previously (Jako et al. 2001). The *Agrobacterium* cells were transformed by electroporation with 50 ng of DNA (napin:*DGAT1*), plated on a selective medium (LB broth supplemented with a final concentration of 50 mg·mL⁻¹ kanamycin), and incubated for 48 h at 28 °C. Single colonies were grown for 16 h (28 °C, 225 rpm) in 5 mL LB broth supplemented with 50 mg·mL⁻¹ of kanamycin and 25 mg·mL⁻¹ of gentamycin. DNA extraction and purification were performed with a Qiaprep Spin Miniprep kit (Qiagen, Valencia, Calif.).

Figure 2. Metabolic implications of altered mtPDHK expression in *Arabidopsis*. Partial suppression of mtPDHK via antisense technology increases the flux of carbon through the TCA cycle both in source and sink organs by easing negative regulation of mtPDH, a key enzyme linking glycolysis and the TCA cycle. Conceptually, this may lead to increased availability of energy and TCA-cycle intermediates that are substrates for anabolic processes, e.g., amino acid and chlorophyll synthesis. Upon increased TCA cycle activity, there is increased export (“push”) of carbon, as citrate, to the cytosol. Via ATP-citrate lyase (ACL), this results in increases in two co-products: (1) cytosolic oxaloacetate which ultimately results in higher plastidial pyruvate and hence, enhanced plastidial fatty acid synthesis for oil assembly and (2) increased cytosolic acetyl-CoA, required to synthesize VLCFAs, isoprenoids, including specific plant growth regulators, aromatic amino acids, acetylated metabolites including sugars, alkaloids, flavonoids etc. necessary for plant growth and development. Partial suppression of mtPDHK provides increased sink strength, thus enhancing productivity and harvest indices. At the same time, mtPDCK suppression can reduce the sink limitation on photosynthesis, allowing higher rates of photosynthesis, providing a mechanism to divert additional photosynthate towards seed oil biosynthesis and other important biosynthetic processes. mtPDH, mitochondrial pyruvate dehydrogenase complex; pIPDH, plastidial pyruvate dehydrogenase; mtPDHK, mitochondrial pyruvate dehydrogenase kinase; MDH, malate dehydrogenase. For all other abbreviations and a more detailed description of metabolic steps impacted by partial suppression of mtPDCK expression, the reader is directed to Weraduwa (2013) from which this figure is modified. Modified with permission from Weraduwa, 2013.

The pSE129A/*DGAT1* plasmid integrity was verified by DNA sequencing following its re-isolation from *A. tumefaciens* and transformation into *E. coli*. The *B. napus* canola cultivars Quantum (Stringham et al. 1995) or DH12075 were then transformed with the *Agro*/pSE129A/*DGAT1* by the cotyledonary petiole method of Moloney et al. (1989). Kanamycin-resistant T₀ transgenic lines were selected, propagated, and segregation analyses performed to identify homozygous T₃ lines, as described previously for other *B. napus* transgenic material (Katavic et al, 2001, Taylor et al., 2001). The oil content and acyl composition of the *B. napus* cv. Quantum transgenic seed lines containing the *A. thaliana DGAT1* were determined as described below and compared to those from non-transformed WT controls.

T. majus DGAT1 and T. majus SDM DGAT1 Lines

The coding region of the *T. majus DGAT1* or *T. majus* S¹⁹⁷-to-A¹⁹⁷ SDM *DGAT1* (Xu et al., 2008) were amplified by PCR with primers: *Xba*I Forward: 5'-TATCTAGAATGGCGGTGGCAGAG -3' and *Kpn*I Reverse: 5'-ATGGTACCTCACTTTTCCTTTAGATTTATC-3' using the same amplification program as described above, and subsequently cloned behind the napin promoter in the respective sites of the pSE129A vector. The final binary vector was verified for integrity by sequencing and electroporated into *A. tumefaciens* as described above and used to transform *Arabidopsis* by the vacuum infiltration method (Bechtold and Pelletier, 1998). Kanamycin-resistant T₁ plants were selected and propagated, and the T₂ and T₃ generation selected and characterized as described by Jako et al., (2001) to identify homozygous T₃ seed lines. These were analyzed for oil content and fatty acid composition as described below. At the same time several independent plasmid-only control transgenics (pSE vector only without *DGAT1* insert) were propagated and analyzed for comparison. The same construct was used to transform *B. napus* cv. DH12075 by the cotyledonary petiole method of Moloney et al., (1989). Kanamycin-resistant T₀ transgenic lines were selected, propagated, and segregation analyses performed to identify homozygous T₃ lines, as described previously for other *B. napus* transgenic material (Katavic et al, 2001, Taylor et al., 2001). The oil content and acyl composition of these SDM *DGAT1* lines were determined as described below and compared to those from non-transformed WT (nt-WT) controls.

mtPDCK Suppression Lines

The *mtPDCK* gene was cloned from *Brassica napus* cv. Quantum by RT-PCR amplification. Total RNA was extracted from young leaves (Wang and Vodkin, 1994) and cDNA produced by reverse transcription (Life Technologies, Inc., 2002, M-MLV Reverse Transcriptase). Using this cDNA and several pairs of degenerate primers (CGGGGTACCTG GGGNNSATGAARCAR and TGCTCTAGATYANGGYAARGG YTCYTS) designed from conserved segments of known *mtPDCK* amino-acid sequences from *Arabidopsis* (CAA07447) and corn (AF038585), a fragment of about 1 kb was amplified by PCR. The fragment was cloned into the TOPO cloning vector (pCR TOPO 2.1, Invitrogen) and fully sequenced in both orientations. DNA sequence analysis revealed that this amplicon shared a high degree of homology with other known *mtPDCK* genes.

The missing termini of the gene were subsequently amplified using a 3' and 5' RACE kit (Life Technologies, Inc., 2002, 3' RACE system and 5' RACE system). The full-length gene was produced by PCR using Vent DNA polymerase (New England Biolabs) and gene specific primers (CTTTCTTCAGCTGGTTCACAC, GACTCCACATACCAATCTC TTAC

CTTCAA, CATAAGGCAGCGTCTCGAGTTCG, AGATGTGGACTTG GGAA CCGCTGAT, GTTATGGTCTGCCTATTAGTCGCTTGTA) designed from the DNA sequence information provided by the RACE-generated fragments. These primers encompassed the start and stop codons. At this stage, two *PmeI* restriction sites were also added by PCR for subsequent anti-sense insertion of the *mtPDCK* gene into expression vectors pSE129A bearing the napin promoter or pBBV-PHAS with the phaseolin promoter (courtesy of Dow AgroSciences) as described in patent CA2474906 C. The antisense (A/S) orientation of the inserted gene was verified by restriction digestions and DNA sequencing.

The final binary vector was verified and electroporated into *A. tumefaciens* as described above and used to transform *Arabidopsis* by the vacuum infiltration method (Bechtold and Pelletier, 1998). Kanamycin-resistant (pSE129A construct) or phosphinothricin-resistant (pBBV-PHAS construct) T₁ plants were selected and propagated, and the T₂ and T₃ generation selected and characterized as described by Jako et al., (2001) to identify homozygous T₃ seed lines. These were analyzed for oil content and fatty acid composition as described below. At the same time several independent plasmid-only control transgenics (pSE129A vector only without antisense *mtPDCK* insert) were propagated and analyzed for comparison. The same constructs were used to transform either *B. napus* cv. DH12075 or cv. Nex710 (Dow AgroSciences) by the cotyledonary petiole method of Moloney et al. (1989). Kanamycin-resistant (pSE129A construct) or phosphinothricin-resistant (pBBV-PHAS construct) T₀ transgenic lines were selected, propagated, and segregation analyses performed to identify homozygous T₃ lines, as described previously for other *B. napus* transgenic material (Katavic et al, 2001, Taylor et al., 2001). The oil content and acyl composition of these A/S *mtPDCK* lines were determined as described below and compared to those from nt-WT controls.

Two-Gene Stack Lines

A two gene construct was created containing the modified *T. majus* SDM *DGAT1* and the *B. napus* *mtPDCK* (in an antisense orientation) genes, both driven by the seed-specific promoter napin, and inserted in the plant transformation vector pSE129A, to produce the vector pGHI-006 (Figure 3). To do this, our original single gene expression cassettes were first inserted into the cloning vector pBluescript SK+ by a blunt ligation to create pNap: *mtPDHK* and pNap: SDM *TmDGAT1*. pNap: *mtPDHK* was then digested by *NotI* and *PspOMI* and the promoter-gene-terminator fragment was cloned into the *NotI*-digested pNap:SDM *TmDGAT1* linear vector to create pGHI-005. A *Sall* fragment containing both expression cassettes was then inserted into the transformation vector pSE129A digested with *SmaI*, by blunt ligation to create pGHI-006. This vector was subsequently used to electroporate *Agrobacterium* as described above and used to transform the *B. napus* canola cv. DH12075 using the cotyledonary petiole method of Moloney et al. (1989). Kanamycin-resistant transgenic lines were screened, selected and characterized as described previously for other *B. napus* transgenic material (Katavic et al, 2001, Taylor et al., 2001). The oil content and acyl composition of these two-gene transformant lines were determined as described below and compared to those from empty pSE129A plasmid controls.

Field Trials

Where indicated in Table 1 and in the text, confined field trials of the *A. thaliana* *DGAT1* in *B. napus* cv Quantum lines were conducted in 2006 and 2007 at Watrous, SK as described by Taylor et al., (2009); field trials of the *B. napus* *DGAT1* in *B. napus* cv DH12075 were conducted at two locations in Alberta (Ellerslie and Vegreville), as described by Weselake et al., et al., (2008). Phaseolin *mtPDCK*-suppressed Nex710 lines were tested in confined field trials at Morden, MB and Saskatoon, SK in plots designed similar to those described by Taylor et al., (2009).

Figure 3. Map of 18 kb 2-gene construct pGHI-006, containing the SDM S¹⁹⁷-to-A¹⁹⁷ *TmDGAT1* (Nast DGAT1) and the *mtPDCK* (PDCK) in sense and antisense orientations, respectively. Both genes are driven by the napin promoter.

Analysis of Seed Oil Content and Composition in Transgenic Lines

Oil content of mature seed from *B. napus* was determined by low-resolution nuclear magnetic resonance spectroscopy (LR-NMR) using a Bruker Minispec mq20 instrument, calibrated with mature *B. napus* seed of known oil content.

As described below, quantifying the fatty acid content of a total lipid extract was the method used to determine the lipid content in pre-weighed *Arabidopsis* seed samples as this was more quantitative and accurate than the NMR method for these extremely small seeds.

The acyl composition of mature seed from *Arabidopsis* and *B. napus* transgenic and nt-WT or plasmid-only pSE129A control plants were determined as follows: Mature seed samples were weighed after being dried overnight at 80 °C, then ground with a Polytron model PT 20, in 4 mL isopropanol:CH₂Cl₂ (2:1 v/v) containing 15:0 triacylglycerol as an internal standard. The debris was washed twice with 1 mL of grinding solvent and the pooled eluants transferred to a test tube. To this was added 0.9% NaCl (1ml) and vortexed. Two ml of CH₂Cl₂ was added, the mixture re-vortexed and centrifuged at 2500 r.p.m. for 3 min. The CH₂Cl₂ layer was removed, the extraction repeated and the CH₂Cl₂ layers combined. CH₂Cl₂: Benzene: Methanol (1:1:1 v/v/v) (1 mL) was added and the sample evaporated to dryness under a stream of N₂. The dried sample was re-suspended in CHCl₃ (1 mL) to give the total lipid extract (TLE). The acyl composition and fatty acid content of the TLE were determined by trans-esterification of the neutral lipid fraction with 3N methanolic HCl, and GC of the resulting fatty acid methyl esters with 17:0 methyl ester as an external standard as previously described (Taylor *et al.*, 2001).

In order to discuss trends in oil content improvements due to different genes/constructs, it was necessary to normalize the oil content relative to the individual control plants within each experiment. This proportional increment in oil content was calculated as:

$$[(\text{Transgenic oil as \% of DW} - \text{Control oil as \% DW}) \div \text{Control oil as \% DW}] \times 100$$
, where the controls are either seed from the corresponding non-transformed WT plants or from empty plasmid transgenics within that experimental set. Data are presented $\pm$ S.D. (n=5-8).

Net oil increases as a % of dry weight were calculated as:

$$[(\text{Transgenic oil as \% of DW} - \text{Control oil as \% DW})]$$
, where the controls are either seed from the corresponding non-transformed WT plants or from empty plasmid transgenics within that experimental set. Data are presented $\pm$ S.D. (n=5-8).

Protein Analyses

Estimates of the crude protein content in seeds from selected 2-gene stack lines and from controls were obtained by the Dumas combustion method (ISO 16634-1:2008 Food products - Determination of the total nitrogen content by combustion according to the Dumas principle and calculation of the crude protein content, Part 1: Oilseeds and animal feeding stuffs. http://www.iso.org/iso/catalogue_detail.htm?csnumber=46328). Total seed nitrogen values (on the basis of % of DW) were multiplied by the conversion factor of 6.25 to arrive at the crude protein content proportions. It is important to note that, while it is one of the industry standard tests for oilseed analysis, the combustion method does not distinguish between nitrogen which is contributed by proteins vs nucleic acids, nitrates or other nitrogenous compounds.

RESULTS

Increases in *Brassica napus* seed oil content in transgenic lines expressing single *DGAT1* (WT or SDM) or silenced *mtPDCK* genes.

DGAT1 Lines

The first *DGAT1* to be cloned from plants, specifically, *A. thaliana*, was simultaneously reported by Zou et al., Hobbs et al., and Routaboul et al., in 1999. All three labs had taken advantage of an *Arabidopsis* EMS mutant, designated AS11 (*dgat1*), which we originally isolated (Katavic et al, 1995). AS11 showed reduced embryo DGAT activity and decreased seed oil with a drastically altered fatty acid composition. The lesion was shown to be an insertional event resulting in a tandem exon 2 repeat. When the WT *DGAT1* gene was over-expressed in AS11, the gene complemented the mutant phenotype, restoring oil content to WT levels and even higher (Jako et al, 2001).

Subsequently, enhancement in oil content has been achieved by over-expression of *DGAT1*s from both *A. thaliana* and *B. napus*, in two different *B. napus* cultivars, Quantum and DH12075, respectively. Seed-specific over-expression of the *A. thaliana* *DGAT1* in *B. napus* cv. Quantum produced homozygous T₃ single insert transgenic lines with absolute and proportional seed oil content increases that were on average, 4.2% and 10.0%, respectively, compared to non-transformed controls under greenhouse conditions (Weselake et al., 2007). In confined field trials over 2 years, the highest proportional oil content increases averaged 7.4% (Table 1). Transformation of *B. napus* cv. DH12075 with an expression cassette containing a modified *B. napus* *DGAT1* fitted with an ER-retention signal showed absolute oil content increases of 2.5-3.5%, which translated to 5.7–7.0% relative increases in a 2-location field trial. These field results were very similar to those observed with the same construct in the greenhouse (3-5% absolute oil content increments) (Taylor et al., 2009). In none of these transgenic experiments were there any significant differences in fatty acid profiles (data not shown). Interestingly, from an agronomic viewpoint, in a field trial in 2003 during which there was a severe drought, the over-expressed *A. thaliana* *DGAT1* was able to rescue a low oil phenotype of *B. napus* cv. Quantum with up to 4.1% absolute and 13.6% relative increases compared to the nt-WT (Weselake et al., 2008).

A *DGAT1* cloned from *Tropaeolum majus* (Xu et al., 2008) was functionally expressed in the yeast *H1246 α MAT* quadruple mutant (*dga1*, *lro1*, *are1*, *are2*) and restored the capability of the mutant host to produce TAGs. The recombinant *TmDGAT1* protein present in lysates of the transformant was capable of utilizing a range of ¹⁴C- labeled acyl-CoA donors and could synthesize ¹⁴C-trierycin from dierycin and erucyl-CoA. Collectively, these findings confirmed that the *TmDGAT1* gene encodes a protein which functions as an acyl-CoA-dependent DGAT1. In plant transformation studies, seed specific expression of the *TmDGAT1* was able to complement the low TAG and fatty acid compositional mutant phenotype of the *Arabidopsis* AS11 (*dgat1*) mutant. When the WT *TmDGAT1* was expressed in either *A. thaliana* (Figure 4), or *B. napus* cv. DH12075, (Figure 5) the proportional oil content averaged about 6% relative to the respective plasmid-only pSE control transformants.

Site-directed mutagenesis (SDM) studies were conducted on 5 putative functional regions/motifs of the *TmDGAT1* enzyme. Of note, mutagenesis of a serine¹⁹⁷ residue to an alanine residue in a putative SnRK1 target site resulted in an average 75% increase in DGAT activity when expressed in yeast (Xu et al., 2008), strong evidence that this putative Ser/Thr protein kinase (negative regulatory) site could be exploited to enhance DGAT1 activity (by preventing phosphorylation at serine¹⁹⁷). Accordingly, over-expression of the *T. majus* SDM S¹⁹⁷-to-A¹⁹⁷ *DGAT1* gene in *A. thaliana* and in *B. napus* cv. DH12075 resulted in average proportional oil content increases of 11.0% (Table 1, Figure 4) and 11.7% (Table 1, Figure 5),

respectively, relative to the plasmid-only pSE controls. Absolute oil content increments were 4.2% and 6.0%, respectively in the two plant hosts. There was no significant difference in the fatty acid profile in either set of transgenics (data not shown). Until this study, there has been no report of the effects of expression of the S¹⁹⁷-to-A¹⁹⁷ SDM *T. majus* *DGAT1*, in *Arabidopsis* or *B. napus*.

Figure 4. Effect of expression of the SDM S¹⁹⁷-to-A¹⁹⁷ *TmDGAT1* on proportional oil increases in *Arabidopsis thaliana*. Proportional oil increases in the SDM *T. majus* *DGAT1* (S2A) transgenic lines are expressed relative to controls obtained by transformation with the empty pSE plasmid alone. Results with transformation with the WT *T. majus* *DGAT1* (TmDGAT) are shown for comparison. All values have been calculated using the formula reported in Materials and Method and are from three replicates. Averages are reported $\pm$ S.D. (n = 5-8).

Repressed Mitochondrial *PDCK* Lines

The first mitochondrial *PDCK* (mt*PDCK*) gene was cloned from *Arabidopsis* by Zou et al., (1999). Transgenic *Arabidopsis* lines having either constitutive (35S) or seed-specific (napin) antisense (A/S) suppression of *mtPDHK* show elevated mtPDH activity (up to 130% 35S; 230% napin), greater respiratory CO₂ release, earlier floral initiation (by as much as 10% = 7-10 d), enhanced seed oil synthesis and accumulation (10% 35S; 30% napin) and an increased harvest index (seed weight enhanced by up 16% 35S, 23% napin) (Zou et al., 1999; Marillia, et al., 2003; Marillia and Taylor, unpublished).

Napin-driven seed-specific expression of A/S *A. thal* mt*PDCK* in *B. napus* cv. Quantum produced transgenic lines which showed, on average, a 12% proportional increase in oil content relative to the plasmid-only controls. Similar experiments conducted with the *B. napus* mt*PDCK* homolog in cv. Quantum resulted in a 3.6% absolute oil increment or a 16% proportional oil content increase (Table 1, Figure 6). Using the phaseolin promoter in *B. napus* cv. Nex710, we observed a net 5% absolute oil increase which translated to a 13% proportional increment in oil (Figure 7). In stark contrast to the case in *A. thaliana* cited above (Marillia et al., 2003), there was no significant change in average seed weights in the greenhouse. In the A/S *B. napus* mt*PDCK* cv. Quantum lines, the average seed weight was 4.38 ± 0.59 mg/seed compared to the nt-WT control at 4.00 ± 0.68 . Similarly, A/S *B. napus* mt*PDCK* transgenics in the Nex710 background had average seed weights of 4.26 ± 0.33 mg/seed vs 3.79 ± 0.31 in the

nt-WT. There were no differences in fatty acid composition between transgenics and controls (data not shown). These results were borne out in 2-site field trials where oil content was proportionally increased by about 12.4% (Table 1). Generally, there were no consistent changes in average seed weight in the field except for line 20-5-3, which showed a remarkable 18% relative increase (4.7 mg) vs the nt-WT Nex 710 (4.1 mg) at that one site. Clearly, the performance of this line merits further testing in future field trials which are beyond the scope of the current study.

Figure 5. Effect of expression of the SDM S¹⁹⁷-to-A¹⁹⁷ *TmDGAT1* on proportional oil increases in *B. napus* cv. DH12075. Proportional oil increases in the SDM *T. majus DGAT1* (N2) transgenic lines are expressed relative to controls obtained by transformation with the empty pSE plasmid alone. Results with transformation with the WT *T. majus DGAT1* (TmDGAT) are shown for comparison. All values have been calculated using the formula reported in Materials and Method and are from three replicates. Averages are reported $\pm$ S.D. (n = 5-8).

Figure 6. Effect of partial seed-specific suppression of *mtPDCK* results on proportional oil increases in *B. napus* cv. Quantum. Proportional oil increases in the anti-sense *mtPDCK* transgenic lines are expressed relative to non-transformed WT controls. All values have been calculated using the formula reported in Materials and Method and are from three replicates. The average increase is reported $\pm$ S.D. (n = 5-8).

Figure 7. Effect of partial seed-specific suppression of *mtPDCK* on proportional oil increases in *B. napus* cv. Nex710. Proportional oil increases in the anti-sense *mtPDCK* transgenic lines are expressed relative to non-transformed WT controls as calculated using the formula reported in Materials and Method and are from three replicates. The average increase is reported $\pm$ S.D. ($n = 7-8$).

INCREASES IN *BRASSICA NAPUS* SEED OIL CONTENT IN TRANSGENIC LINES EXPRESSING THE TWO-GENE CONSTRUCT CONTAINING THE SDM *T. MAJUS DGAT1* PLUS A/S *B. NAPUS* *MTPDCK*

The two-gene construct driven by the napin promoter, contained the *T. majus* SDM S¹⁹⁷-to-A¹⁹⁷ *DGAT1* in a sense orientation and the *B. napus* *mtPDCK* in an anti-sense orientation. The rationale was that there would be increased carbon flux into fatty acid precursors (A/S *mtPDCK*), as well as an effect on the efficiency of oil deposition (SDM *DGAT1*), i.e., a “push-pull” effect. As shown in Figure 8, the four best two-gene transgenic lines showed consistent proportional oil increases of about 24% based on net oil increments of 11-12% compared to pSE plasmid-only transformants (Figure 9). This is very close to an additive response of those found by expression of each individual gene in a number of backgrounds (Table 1; Figure 10).

With respect to the other major seed storage component, protein, there were significant differences in protein content compared to the controls (Figure 11); for example, line 6-19M-8-1 showed more than a 5% increase in seed protein content compared to controls.

There were no significant differences in average 10-seed weights between the two-gene transgenics and controls. Comparing the seed weights of the highest and the lowest oil increase lines with the controls, line 6-19M-8-1 and 6-18P-10-4 had average 10-seed weights of 51.9 ± 5.6 mg and 48.9 ± 2.0 mg, respectively, compared to the control which had a 100-seed weight of 51.2 ± 2.9 mg (Figure 11).

Figure 8. Effect of partial seed-specific suppression of *mtPDCK* combined with expression of the SDM S^{197} -to- A^{197} *TmDGAT1* on proportional oil increases in *B. napus* cv. DH12075. Proportional oil increases in the 2-gene transgenic lines are expressed relative to controls obtained by transformation with the empty pSE plasmid alone. Proportional oil increases have been calculated using the formula reported in Materials and Method and are from three replicates. The average increase is reported $\pm$ S.D. ($n = 4-8$).

Figure 9. Effect of partial seed-specific suppression of *mtPDCK* combined with expression of the SDM S^{197} -to- A^{197} *TmDGAT1* on net oil increases (as % of dry weight) in *B. napus* cv. DH12075. Net oil increases in the 2-gene transgenic lines are expressed relative to controls obtained by transformation with the empty pSE plasmid alone. Net oil increases (% DW) have been calculated using the formula reported in Materials and Method and are from three replicates. The average increase is reported $\pm$ S.D. ($n = 4-8$).

Figure 10. Comparison of effect on proportional oil increases in *B. napus* cv. DH12075 obtained by expression of the 2-gene construct (partial seed-specific suppression of *mtPDCK* combined with expression of the SDM S¹⁹⁷-to-A¹⁹⁷ *TmDGAT1*) with that obtained by transformation with the individual genes alone (*Tm S2A DGAT1* or *A/S Bn mtPDCK*). Proportional oil increases are expressed relative to controls obtained by transformation with the empty pSE plasmid alone and have been calculated using the formula reported in Materials and Methods and are from three replicates. The average increase is reported $\pm$ S.D. (n = 4-8).

Figure 11. Effect of partial seed-specific suppression of *mtPDCK* combined with expression of the SDM S¹⁹⁷-to-A¹⁹⁷ *TmDGAT1* on average seed weight and protein content in *B. napus* cv. DH12075. Average 10-seed seed weights (mg) in the 2-gene transgenic lines are expressed relative to controls obtained by transformation with the empty pSE plasmid alone. Weights were determined on 100-125 seed samples analyzed in triplicate and averages are reported $\pm$ S.D. (n = 4-8). Crude protein content was determined using the Dumas combustion method as described in Materials and Methods (n = 4-6).

Figure 12. Effect of partial seed-specific suppression of *mtPDCK* combined with expression of the SDM S¹⁹⁷-to-A¹⁹⁷ *TmDGAT1* on fatty acid composition of *B. napus* cv. DH12075 seed oil. Fatty acid composition is reported as total saturated, mono-unsaturated or poly-unsaturated fatty acid proportions in seed oil from the 2-gene transgenic lines relative to controls obtained by transformation with the empty pSE plasmid alone. Oil analyses were performed in triplicate and averages are reported $\pm$ S.D. (n = 4-8).

With respect to the oil composition, the transgenics showed a slight increase in monounsaturated fatty acids (2.3%, 2% of this is oleic acid), a concomitant decrease (2.5%) in polyunsaturated fatty acids, and essentially identical proportions of saturated fatty acids compared to the pSE controls (Figure 12). Any increment in oleic acid is a positive change in canola germplasm improvement work. However, further study is required to see whether this small increment is observed under field conditions.

DISCUSSION

While beyond the scope of the current study, it is important to note that in breeding *B. napus*, the use of heterosis in high vs. low oil lines, and QTLs to map the relationship of specific genetic loci to oil content, continue as an effective, but not necessarily rapid, way to increase crop yield and oil content. Studies reported over the last decade on the use of QTLs in breeding for oil content improvements include those by Delourme et al., (2006), Qiu et al., (2006), Cao et al., (2010), Sun et al., (2012), Wang et al., (2013) and Jiang et al., (2014), and the reader is advised to consult these and the references therein for a comprehensive treatment of these approaches.

Single Gene Transfers for Improvements in Oil Content

Though certainly not a comprehensive list, the directed over-expression of single lipid metabolism-related genes to improve oil content in *Arabidopsis*, *B. napus* and other oilseeds

include: expression of a yeast *SLC1-1* (lyso-phosphatidic acid acyltransferase, *LPAAT*; Zou et al., 1997; Taylor et al., 2001), homeologous *B. napus* *LPATs* (Maisonneuve et al., 2010); a yeast glycerol-3-phosphate dehydrogenase (Vigeolas et al., 2007), diacylglycerol acyltransferase 1 (*DGAT1*, Bouvier-Nave et al., 2000; Jako et al., 2001; Weselake et al., 2007; Taylor et al., 2009), diacylglycerol acyltransferase-2 (*DGAT2*, Lardizabal et al., 2008; Zhang et al., 2013) and phospholipid: diacylglycerol acyltransferase1 (*PDAT1*) for leaf TAG (Fan et al., 2013). By re-targeting the Arabidopsis homomeric cytosolic form of Acetyl-CoA Carboxylase (*ACCase*) to plastids, there was a 5% increase in oil reported (Roesler et al., 1997).

The complex cascade of events/interactions among transcription factors is still unfolding as they relate to directing fatty acid synthesis and oil accumulation. Nonetheless, there have been numerous studies of targeted over-expression of transcription factors to enhance oil, including: *Zea mays Leafy cotyledon 1* (*LEC1*, Shen et al., 2006); *Castor Leafy cotyledon 2* (*LEC2*, Kim et al., 2013); soybean *GmDof4* and *GmDof11* (DNA binding with one finger) (Wang et al., 2007), *BnGRF2* (*Brassica napus growth-regulating factor 2*-like gene; Liu et al., 2012), *WRINKLED1* (Liu et al., 2010), *FUS3* (Wang et al., 2007) and *SHOOTMERISTEMLESS* (Elhiti et al., 2012).

Mutant studies have implicated pyruvate kinase (Andre et al., 2007), *FatA* thioesterases (Moreno-Perez et al., 2012), cytosolic glucose-6-phosphate dehydrogenases (Wakao et al., 2008) and *GLABRA2* (Shen et al., 2006; Shi et al., 2012) as having positive influences on seed oil accumulation in *Arabidopsis*. These are but a few examples; an examination of the extensive literature using *A. thaliana* mutants to identify (often via complementation) key genes involved in aspects of fatty acid metabolism, oil accumulation and/or seed development, is beyond the scope of this study.

In a recent report by Chen et al., (2011), a study was made of Kennedy pathway enzyme activities and their correlation with oil content in *B. napus*. Using lines with relatively high, medium or low oil, sampled over the span of 18-46 days after planting, and monitoring Kennedy pathway enzyme activities, they showed that peak values and averages of the lowest KP enzyme activity (LEA) in the lines were significantly correlated with seed oil content, indicating that KP enzyme efficiency is tightly associated with oil deposition. The LEA (which can be regarded as indicator to the TAG bioassembly efficiency) was, in most cases, *DGAT1*. This further supports over-expression data (discussed below) which confirm that *DGAT1* can be viewed as a bottleneck/rate limiter for oil deposition.

Interestingly, the first report of transgenic expression of *DGAT1* was one wherein the *A. thaliana DGAT1* was ectopically expressed not in seeds, but in leaves of tobacco where endogenous oil is typically a few percent by weight (Bouvier-Nave et al., 2000). The authors reported increases in TAG in leaf lipid droplets of 3.6-fold on average, in T₁ leaves of the best 13 transformants, with the best transformant showing a remarkable 7-fold increment in leaf TAG compared to nt-WT plants. This increase was strongly correlated with *AtDGAT1* transcript expression.

Following this, over-expression of WT *A. thal DGAT1* in *Arabidopsis* resulted in an average of 5.1% absolute and 17.5% proportional increments in seed oil content in the best 8 single-insert events, relative to plasmid-only pSE controls; multiple insert lines showed a notable 21% proportional increase (Jako et al., 2001). These results correlated well with *DGAT1* transcript levels and suggested a gene-dosage effect favored by multiple inserts. *B. napus* transgenics expressing a modified *B. napus DGAT1* (engineered with an ER-retention peptide) showed up to a 7% relative seed oil increase in a 2-location confined field trial, similar to the improvement

observed in the greenhouse (Weselake et al. 2008). This demonstrated that the capacity to improve oil content by this targeted approach was consistent, stable and able to translate exceptionally well from greenhouse to field. In contrast, silencing of *DGAT1* in tobacco caused a reduction in seed oil content (Zhang et al., 2005) which equally confirms the direct link between the level of *DGAT1* expression, *DGAT1* enzyme activity and oil deposition.

In the current study, over-expression of WT *A. thaliana* or *T. majus* *DGAT1*s in *B. napus* showed on average, 6-7% relative increments in oil content (Table 1). These results bear out past demonstrations of improvements in seed oil content using WT *DGAT1* genes.

There have also been several studies wherein *DGAT2*-like proteins from fungi or marine sources (having no significant homology to *DGAT1*s from plants) have been expressed in various plant hosts: The expression of an *Umbelopsis ramanniana* *DGAT2A* in soybean resulted in a 7.5% proportional increase in oil content (Lardizabal et al., 2008). More recently, a *TaDGAT2* cloned from the oleaginous marine protist *Thraustochytrium aureum*, was expressed in either WT or the *fad3/fae1* mutant *A. thaliana* seeds. This resulted in little change in seed oil content, but a striking increase in oleic acid proportions, up to 50% of total fatty acids in the *fad3/fae1* background (Zhang et al., 2013). It is interesting to note that neither the *Umbelopsis* nor the protist *DGAT2* transgenics exhibited striking differences in oil content in dicots. The recent transgenic expression of the *Umbelopsis ramanniana* *DGAT2* in maize using an embryo-enhanced promoter resulted in small but significant increases in kernel oil of up to 0.7% by weight (a proportional increase of 19%), while overexpression of a *Neurospora crassa* *DGAT2* gene resulted in slightly higher oil increases up to 0.9% by weight (a proportional increase of 26%) (Oakes et al., 2011). It is critical to remember that in corn, the embryo is only a small part of the kernel, and therefore the overall gain in oil is small. Thus, the capacity to strongly improve seed oil content by over-expression of individual non-plant *DGAT2* genes is questionable.

The SnRK1 (Sucrose non-fermenting (SNF)-related protein kinase-1) proteins are a class of Ser/Thr protein kinases that have been implicated in the global regulation of carbon metabolism in plants (Halford and Hardie, 1998). It has been hypothesized that the SnRK1 complex can be regulated by different metabolites according to the organs or tissues involved, (source or sink) and that SnRK1s are at the very center of energy metabolism control (Polge and Thomas, 2006). In the developing seed (sink), we conjectured that such metabolite regulation may be controlled by the size of the DAG pool (DAG is implicated as an initiator in a number of signal transduction cascades) or the relative ratio of key Kennedy pathway intermediates, such as e.g., the PC/DAG or TAG/DAG ratios. If, for example, the DAG available for synthesis of membrane and other polar lipids (e.g., phosphatidyl-cholines, -ethanolamines, -serines and -inositols) becomes limiting during the exponential phase of seed development, then a regulatory mechanism for diverting DAG to membrane lipids rather than TAG synthesis (i.e., down-regulation of *DGAT* activity), might be necessary (Xu et al, 2008). *DGAT1* could join a growing list of key enzymes in different plant metabolic pathways, including nitrate reductase, 3-hydroxymethyl -3-methylglutaryl-CoA reductase, sucrose phosphate synthase and trehalose phosphate synthase 5, which are coordinately regulated by SnRK1-catalyzed post-translational enzyme phosphorylation (Xu et al., 2008).

The current study is the first to report the effects of expressing a *DGAT1* possessing a mutation (S¹⁹⁷-to-A¹⁹⁷) in a putative SnRK1 site, with respect to seed oil deposition. The expression of the mutated *TmDGAT1* in *B. napus* resulted in a proportional increase in oil

content roughly twice that observed in experiments over-expressing the WT *T. majus* *DGAT1* (Figure 5). This mirrored the results of expression of the WT *Tm* *DGAT1* vs the SDM S¹⁹⁷-to-A¹⁹⁷ *DGAT1* in yeast, where the microsomal fractions from transformant lysates showed that the SDM *DGAT1* activity averaged 75% higher than that observed from expression of the WT *T. majus* gene (Xu et al., 2008). Collectively, this provided strong justification for selecting the SnRK1 site-mutated, rather than the WT, form of the *T. majus* *DGAT1* for our gene stacking experiments in *B. napus*, as described below.

At about the same time that our work on the significance of the S¹⁹⁷ residue in *DGAT1* was published, a study in corn showed that a high-oil QTL (*qHO6*) which positively correlated with maize seed oil and oleic-acid contents, encodes an acyl-CoA:diacylglycerol acyltransferase (*DGAT1-2*), which catalyzes the final step of oil synthesis. The study demonstrated that a phenylalanine insertion in *DGAT1-2* at amino acid residue 469 (F⁴⁶⁹) is responsible for the enhancement in these two traits. The *DGAT1-2* allele with F⁴⁶⁹ was shown to be ancestral, whereas the allele without F⁴⁶⁹ is a more recent mutant selected by domestication or breeding. Ectopic expression of the high-oil *DGAT1-2* allele increased oil content from 3-4%, typically found in domestic maize cultivars, to 6-7%, an increase of up to 41% (Zheng et al., 2008).

While counter-intuitive, rather than increasing carbon loss, the enhanced respiration (increased mitochondrial PDH and TCA cycle activity) afforded by transgenic silencing the negative regulator of the PDH complex (*mtPDCK*) in *Arabidopsis* led to enhanced oil accumulation and a higher yield (seed weight) as reported in section 3.1.2, (Zou et al., 1999a; Marillia et al., 2003). Subsequent experimentation wherein, under control of the napin promoter, we silenced the *B. napus* *mtPDCK* in *B. napus* cvs. Quantum and Nex710, showed strong proportional increases in oil content (13-15%) compared to nt-WT plants (Figure 6). This confirmed that a useful approach to effect improvements in oil content is the suppression of seed *mtPDCK* to limit the negative regulation of the PDH complex activity, the entryway of photosynthetic carbon into the respiratory TCA cycle for the production of ATP and reducing equivalents. We have recently reported preliminary findings that transgenic *Arabidopsis* having increased respiratory flux through partial suppression of *mtPDHK* show 2-3 times more plant and oil productivity and an enhanced harvest index at high CO₂ (700 ppm vs 380 ppm) (Grodzinski et al., 2011; Weraduwege, 2013; Dahal et al., 2014). Further work is in progress, but these initial findings suggest that the anabolic properties of dark respiration can be harnessed, allowing additional photosynthate produced at higher atmospheric CO₂ to be more efficiently diverted to the production of plant oils.

Gene Stacking

Que et al. (2010) have recently reviewed the current status of trait stacking in crops like canola, cotton and corn. They have focused on the myriad of transgene combinations (formed by conventional breeding, i.e., the crossing of a transgenic plant (event) containing individual transgenes with other event(s) containing single or double transgenic traits) having to do with stacked trait cultivars with increasing numbers of genes for insect- and herbicide- tolerance to expand the scope of insect pests and weeds that can be combatted (see Que et al., (2010), their Table 1). As reported by James (2012), stacked traits are an important feature of biotech crops: 13 countries planted biotech crops with two or more traits in 2012. Globally, around 33 million ha, equivalent to 26% of the 170 million ha devoted to biotech crops, were stacked trait

plantings. The need to stack multiple gene events is becoming more complex than ever in this realm; for example, in corn, at least 8 trait genes have been combined to provide for combined weed control and at least two modes of action for controlling four major pests (Genuity/SmartStax™ by Monsanto and Dow AgroSciences).

With respect to gene stacking, Taverniers et al., in a 2008 review have said: “....*there are many types, definitions, and perceptions of stacking. These include: (1) stacking of traits and (2) stacking of events, which are the most widely accepted perceptions of stacking, and (3) stacking of genes, which from the analytical and traceability point of view may be a more appropriate perception.*”, and herein, we have adopted definition (3) for purposes of discussion and refer to it as “gene stacking”.

Multi-gene expression cassette transformations where a single construct harbours two or more genes can be performed relatively easily. Commercial examples include Herculex™ I, Herculex™ RW and Agrisure™ CB/LL in corn and Vistive™ Gold in soybean (International Service for the Acquisition of Agri-biotech Applications, 2013). A new approach: trait stacking via targeted genome editing, has been reported in maize by Ainley et al. (2013). They demonstrated that the combination of high-efficiency targeted genome editing driven by engineered zinc finger nucleases (ZFNs) with modular ‘trait landing pads’ (TLPs) would allow ‘mix-and-match’, on-demand transgene integration and trait stacking in crop plants. They illustrated the utility of nuclease-driven TLP technology by applying it to the stacking of two herbicide resistance traits. Both herbicide resistance traits co-segregated, thereby demonstrating a TLP linkage of the two independently transformed transgenes.

Gene stacking is especially applicable in metabolic engineering of plants since most metabolic processes and biochemical pathways involve numerous genes interacting with each other. Multi-gene transfers have enabled the import of entire metabolic pathways, the expression of entire protein complexes and the development of transgenic crops simultaneously engineered to produce a spectrum of added-value compounds (Naqvi et al., 2009). Commercial successes include the engineering of the entire pathway for provitamin A (beta carotene) biosynthesis in rice endosperm by stacking three carotenoid genes (“Golden Rice”, Ye et al., 2000) and the “Blue Rose”, possessing modified flower color, produced by stacking two genes in the anthocyanin biosynthetic pathway to alter flower pigmentation. This gives the biotech rose flowers the capacity to accumulate delphinidin-based anthocyanins, resulting in novel shades of blue rose petals (Tanaka et al., 2009). The transgenic expression of a multi-gene construct has resulted in the reconstitution of the polyhydroxybutyrate biosynthetic pathway in *Arabidopsis* (Kourtz et al., 2007) and in the high biomass crop, switchgrass (Somleva et al., 2008).

Gene Stacking for Improvements in Oil Composition

In the area of seed lipid biosynthesis, there are numerous reports of stacking genes for oil quality/fatty acid composition. This topic has been extensively reviewed of late (Haslam et al., 2013) and so, only a few selected examples follow:

In *B. napus*, simultaneous over-expression of an acyl-ACP thioesterase (*FatB*) and silencing of eight putative acyl-acyl carrier protein desaturases (SADs) using artificial microRNAs, was shown to increase saturated fatty acid proportions in the seed oil (Sun et al.,

2014). Total saturated fatty acid content was increased from 7.4% in the control to 37.3–45.6% in the transformed lines.

Upon expression in canola, the stacking of $\Delta 12$ and $\Delta 6$ desaturases from the fungus *Mortierella alpina* led to seeds accumulating of over 40% γ -linolenic acid (GLA) and 2% stearidonic acid (SDA) (Liu et al., 2001). To increase metabolic flux toward SDA synthesis, Ursin (2003) stacked the *M. alpina* *FAD2* and *FAD6* with the *B. napus* $\Delta 15$ desaturase (*FAD3*) genes, which resulted in GLA and SDA accumulations of 23% and 15%, respectively.

Value-added seed oil compositional changes have been made in soybean by gene stacking: suppressing the expression of all three *GmFAD3* genes with a single RNA interference construct generated an ultra-low linolenic phenotype. Simultaneous down-regulation of soybean *FAD2-1A* and *-1B* resulted in lines with oleic acid contents exceeding 80% (Clemente and Cahoon, 2009). The coordinated expression of the *FAD6* from borage with the *FAD3* from *Arabidopsis* produced an oil with GLA, linolenic acid, and SDA proportions of 5.8%, 33.5%, and 21.6%, respectively (Eckert et al., 2006).

The most successful examples in the extreme have been in engineering the production of long-chain PUFAs in members of the *Brassicaceae*. Wu et al., (2005). produced transgenics containing significant amounts of arachidonic acid (AA) and eicosapentaenoic acid (EPA) by a step-wise metabolic engineering strategy: By a series of transformations in *B. juncea* using constructs containing increasing numbers of transgenes, they achieved incremental production of AA up to 25% and EPA up to 15%. More remarkably, they re-constituted the entire DHA biosynthetic pathway in *B. juncea* using a single construct containing 9 transgenes, leading to the production of EPA levels up to 15% and DHA levels up to 1.5% in seeds. More recently, the engineering of *Arabidopsis* to produce long-chain PUFAs, involved the introduction of a completely new pathway comprised of five additional enzymatic steps, plus enhancement of endogenous precursor pathways (Petrie et al., 2010, 2012; Ruiz-Lo'pez et al., 2012), perhaps the most complex metabolic engineering result achieved in plants to date. The amount of DHA produced exceeded 12% which is the level at which DHA is generally found in bulk fish oil. By projection, if transferred to canola, the authors reported that one hectare of a crop containing 12% DHA in the seed oil would produce as much DHA as approximately 10,000 fish. Clearly, this is a breakthrough in the development of sustainable alternative sources of DHA, and this was demonstrated by the subsequent transfer of this DHA pathway to the new oilseed crop, *Camelina sativa* (Petrie et al., 2014) which has yields as high as canola and mustards.

Gene Stacking for Improvements in Oil Content

There have been few reports of oil content enhancement through stacking transgenes in oilseeds. In *Arabidopsis*, *LEAFY COTYLEDON1* (*LEC1*) and *LEC1-LIKE* (*L1L*) are key regulators of fatty acid biosynthesis. Over-expression of *AtLEC1* orthologs from *B. napus* (*BnLEC1* and *BnL1L*), caused an increased fatty acid level in transgenic *Arabidopsis* plants, but these exhibited severe developmental abnormalities. Using a truncated napin A promoter (which retains the seed-specific expression pattern but with a reduced potency) to drive the co-expression of *BnLEC1* and *BnL1L* in transgenic canola resulted in proportional increases of 2–20% in the seed oil content without any detrimental effects on major agronomic traits (Tan et al., 2011). Co-expression of *WRINKLED 1* and *DGAT1* in *Arabidopsis* under control of either

the *A. thal* FAE1 or *B. napus* napin promoter gave 8-11% relative seed oil content increases compared to nt-WT (Kim et al., 2012).

Recently, it has been shown that Phospholipid: Diacylglycerol Acyltransferase1 (PDAT1) is critical for TAG biosynthesis in leaves. Over-expression of *PDAT1* in *Arabidopsis* leaves led to oil droplet fusion and thus over-expansion, while ectopic expression of oleosin was found to promote the clustering of small oil bodies. When ectopically co-expressed, *PDAT1* plus *oleosin* genes enhanced *Arabidopsis* leaf TAG content by up to 6.4% of the dry weight without affecting membrane lipid composition and plant growth (Fan et al., 2013). The extreme Xerophyte *Tetraena mongolica* Maxim has high oil content in the stems. In a similar vein to the Fan et al., study, two *DGAT1*s from this species were cloned and overexpressed. In a 2-gene construct containing both *TmDGAT1a* and *TmDGAT1b*, increases in oil content in soybean hairy roots ranged from 37% to 85%, while co-expression in *T. mongolica* calli resulted in increases in oil from 59% to 108%. Accompanying altered fatty acid profiles had an increase in linoleic and palmitic acids with a dramatic decrease in 18:3. The authors conclude that combined over-expression of these two genes may both increase oil content and alter fatty acid composition (Li et al., 2013). However, it is difficult to compare these examples of stacking results with ours, as in the former, the tissues chosen for expression are not cotyledons/seeds but vegetative (leaves or roots), or undifferentiated calli. Nonetheless, these gene combinations hold promise as a means to enhance the oil content of vegetative biomass for the energy and animal feed sectors.

In multi-step biosynthetic pathways there are usually rate-limiting steps that control the flux through the whole pathway. In its simplest form, this can be overcome by either increasing the amount of the rate-limiting enzyme or by expressing a variant enzyme that is more active (Moeller and Wang, 2008).

We made use of both principles in the current study: our combined gene transfer approach to enhance *B. napus* oil content included over-expression of a variant gene encoding one of the key rate-limiting steps in the Kennedy pathway for oil assembly (SDM *T. majus* *DGAT1*) with anti-sense suppression of *mtPDCK*, resulting in up-regulation of the activity of *mtPDH*, which universally controls the flux of photosynthetic carbon through the mitochondrial respiration pathway. Our stacking results are superior to the best individual transgenic effects using single gene constructs to over-express either the *A. thaliana* *DGAT1*, the *TmDGAT1*, or its variant SDM *S*¹⁹⁷-to-*A*¹⁹⁷ *TmDGAT1* in *Arabidopsis* or canola, or to effect suppression of *mtPDCK* in canola. Indeed, the enhancement of oil content (almost 24%) was near-cumulative in the 2-gene stack lines compared to the best single gene events (Figure 10). Furthermore, the proportional improvement in seed oil content in our best 2-gene transgenic lines are consistently high (>22%), and therefore somewhat superior to the best effect afforded by the co-expression of the *BnLEC1* and *BnLec1*-like genes in canola (2-20%; Tan et al., 2011) or *wrinkled 1* + *DGAT1* in *Arabidopsis* seed (Kim et al., 2012).

Effects on Seed Weight

There do not appear to be any directed studies of the effects of gene stacking to specifically address seed weights in oilseeds.

To our knowledge, the most dramatic increase in seed size in canola has been by a single gene transfer- the seed-specific expression of the *Rev* gene (plant growth and/or development -

associated gene, *Revoluta*TM) which resulted in 5.6 to 59.8% increments relative to their null siblings in field trials (Derocher and Nugyen, 2007; Patent application CA2633988A1).

In our studies, there were significant increases in average seed weight upon expression of the *A. thaliana* *DGAT1* in WT *Arabidopsis* (averaging 20.6% in multiple and 5% in single insert lines) compared to non-transformed pSE controls (Jako et al., 2001). However, there were little or no consistent differences in this trait in *AtDGAT1* *B. napus* transgenics in the greenhouse. Similarly, the *A/S mtPDCK Arabidopsis* transgenics showed strong average seed weight increments of up to 16% upon constitutive expression and up to 23% under napin control (Marillia et al., 2003), but the trait did not translate well to *B. napus* (data not shown).

In our *B. napus* two-gene transgenic lines, there was no significant difference with respect to average seed weight compared to the controls, despite the fact that oil content was markedly improved.

Why the individual or stacked transgenes do not have the same stimulating effect on seed weight in *B. napus* as they do in *Arabidopsis* may be partially due to the fact that the two hosts are propagated in a dissimilar way. *B. napus* transgenics are propagated, partially pruned and bagged (to ensure “selfing” and not out-crossing) during seed development and through to maturity in the greenhouse. This more than likely affects the overall “yield”. This may be the most important difference; in *Arabidopsis*, even though plants are coned at the bolting stage until seed harvest, there is no pruning during the seed development phase. Recently, it has been suggested that in *Arabidopsis*, starch turnover is functionally linked to cell division and differentiation rather than to developmental or storage functions specific to embryos; the situation is more complicated than previously thought. The pathways of embryo starch metabolism are similar in several respects to those in *Arabidopsis* leaves an entirely new way of looking at the role of embryonic starch (Vasilios et al., 2010). Thus, while the reasons for the differential effects of *DGAT1* over-expression and *mtPDCK* suppression on seed weight between *Arabidopsis* and *B. napus* require further investigation, it may, to some extent, have to do with differences between the two species in the degree to which these genetic modifications affect how starch is partitioned and channeled between oil synthesis and cell division/proliferation in the developing seed. This requires further comparative study.

Effects of the 2-Gene Stack on Protein Content

We compared the protein contents of the highest and the lowest oil increase lines with the control. Line 6-19M-8-1 and 6-18P-10-4 had average protein contents of $36.7 \pm 0.9\%$ and $31.0 \pm 1.4\%$, respectively, compared to the control, which had a protein content of $33.2 \pm 0.2\%$. Thus, there were interesting differences compared to controls: In the case of the high oil increase line 6-19M-8-1, protein was also significantly increased compared to the control, while in the lowest oil increase line 6-18P-10-4, the protein content was slightly lower than the control.

What is not clear, for example, is why line 6-19M-8-1 has proportional increments in both oil and protein compared to the controls and yet average seed weights are not significantly different. This would suggest that other factors contributing to seed weight such as hull and integument thicknesses, and the proportions of secondary seed components like phytate and sinapine, may be differentially affected in the 2-gene transgenics compared to the controls.

FUTURE STUDIES AND CONCLUSION

We anticipate that proper assessment of the trends in seed yield in our 2-gene stack *B. napus* transgenics will require large-scale field trails which are planned for the future. This will also give us a better opportunity to assess the effects of the combined genes on the collective proportions of oil, protein and other seed components in a field environment. This will be the true test of the value of combining the two technologies. Additionally, top-down metabolic flux analyses (Ramli et al., 2002; Weselake et al., 2008) of our best T₃ two-gene stack lines are currently underway to examine the relative contributions of up-regulation of fatty acid synthesis activity (Block A) vs. TAG assembly activity (Block B), with respect to the enhanced oil phenotypes.

In conclusion, our results show that at the greenhouse level, stacking *DGAT1* with suppression of *mtPDCK* is a means to effect strong improvements in oil content in canola. While rigorous field testing is still required, this approach holds promise for testing in other oilseed crops as well.

ACKNOWLEDGMENTS

The authors acknowledge the contributions of past collaborators to some of the single-gene work reviewed in this manuscript, including the labs of Dr. R.J. Weselake (Universities of Lethbridge and Alberta), Dr. J. Harwood (Cardiff University) and Drs. B. Micallef and B. Grodzinski (University of Guelph). We also thank Dr. T. Fawcett for the seed protein analysis of the 2-gene transgenic lines. This is NRCC manuscript # 56088.

ABSTRACT

It is well known that genetic variations can in part affect human oral health. Periodontitis is a common dental noncommunicable disease (NCD). According to the World Health Organization, periodontitis affects 20% of the world population. Periodontal inflammation could eventually induce alveolar bone resorption, causing tooth mobility and tooth loss, which ultimately affects oral function, oral health and the individual's quality of life. Family study, twins study and linkage analysis in the early years revealed that genetic influence contributes to periodontal disease. Since the first single nucleotide polymorphisms (SNP) study on chronic periodontitis in 1997, many genetic loci were found to be associated with periodontitis, including IL-1, Fc gamma receptor and complement component 5 genes. Population structure or earlier investigations employing a less desirable sample size may lead to various limitations or bias and therefore diverse results. Meta-analysis reports have proved the association between periodontitis and SNPs in some regions, such as *IL1* and *HLA*. With development of the technologies, multiple genes can be analyzed in a single assay, and even whole genome SNPs can be screened. Seven genome-wide association studies (GWASs) investigated the potential genetic risk locus for periodontitis and found *GLT6D1* is significantly associated with aggressive periodontitis. In the future, whole genome sequencing, together with replication in multiple populations and functional studies, could potentially disclose the nature of periodontitis as an NCD.

1. PERIODONTITIS - A BRIEF INTRODUCTION

Periodontitis is characterized by periodontal attachment destruction and alveolar bone loss. The common clinical symptoms include gum swelling, increased tooth mobility and excessive gingival recession, which reduce the chewing function, lead to aesthetic problems and affect the patient's quality of life.

It is one of the most common oral diseases and one of the major causes of tooth loss. The WHO reported in 2003 that up to 20% of the global human population has suffered from periodontal diseases (Petersen, 2003). The prevalence of 40-66.5% of subjects with community periodontal index of more than 2 in any one surveyed sextant, indicative of mild to severe periodontal inflammation, was reported in different adult populations of more than 30 years old. Approximately 8-11% of the total population is affected by severe chronic periodontitis (Hugoson et al., 2008; Eke et al., 2012).

Chronic periodontitis (CP) and aggressive periodontitis (AgP) are two of the major subtypes of periodontitis (Figure 1). CP is the most prevalent form of periodontitis in middle-aged to elderly adults and often has slow to moderate disease progression rate. It is caused by inadequate oral hygiene and may be modified by systemic diseases, such as diabetes, or other risk factors, like smoking or stress (Armitage, 2004). Different from CP, AgP is a periodontitis with prevalence ranging from 0.1% to 3.0% in adolescents and young adults, characterized by rapid progression and familial aggression (Eres et al., 2009).

Figure 1. Clinical cases of periodontitis: A) Chronic periodontitis – 42-year-old female suffering from severe form of the disease started approximately two years before presentation; B) Aggressive periodontitis – 20-year-old female suffering from generalized form of the disease. Human periodontitis in general is characterized by gum inflammation, tooth attachment apparatus breakdown including periodontal attachment loss, drifting and even tooth loss, which is observable from clinical pictures and radiographs of both cases shown. Note that case A lost the lower right second molar with radiographic sign of combined periodontal-endodontic lesion in lower left lateral incisor. On top of what was described earlier, both individuals have poor oral hygiene and calculus deposition.

Dental plaque or the oral biofilm, inhabited by various pathogens, is regarded as the etiological factor of periodontal disease. The subgingival bacterial biofilm, through interactions with periodontal lining cells, triggers the host inflammation and induces local innate and adaptive immune responses. However, periodontal destruction is not caused by the bacteria-host interaction *per se*, and not all individuals are equally susceptible to periodontitis despite the presence of plaque bacteria. People who never learn tooth brushing as a proper healthy lifestyle practice, however, are at higher risk to develop gingivitis or periodontitis but could remain periodontally healthy throughout life (Loe et al., 1986).

Either hyper- or hypo-responsiveness of the immune system, reflective of inappropriate host response toward periodontal disease pathogens, especially the overreaction, was believed to be the driver for destruction of the tooth-supporting tissue and eventually tooth loss, provided the disease remains untreated (Kinane et al., 2007). The variation of host susceptibility is determined by a multitude of factors. Smoking, diabetes, stress, gender, specific pathogenic bacteria and other risk factors have been reported to affect the pathogenesis and the severity of periodontitis (Grossi et al., 1994; Ng et al., 2006). Nevertheless, individual differences cannot be explained exclusively by the exposure to any one or a combination of these factors alone. Along such lines, genetic risks of periodontal disease are investigated to map out the individual periodontitis susceptibility variations.

2. REVIEW OF GENETIC STUDIES ON PERIODONTITIS

The genetic risks for periodontitis have been studied for decades. Periodontitis was once regarded as simple Mendelian disease in the early years. However, except for “periodontitis as a manifestation of systemic disease,” most periodontitis cases have been realized later as a complex common disease affected by multiple genes and environmental factors. The candidate gene approach and genome-wide study without pre-investigation hypothesis helped build some genetic background on periodontitis. Here we review the history of periodontitis genetic studies and summarize the appreciation of the situation so far.

2.1. Periodontitis Associated with Other Genetic Disorders

Genetic factors play an important role in some aggressive forms of periodontitis secondary to particular bodily conditions, which are termed “periodontitis as a manifestation of systemic disease.” Many of these systemic early-onset diseases are monogenic disease following Mendel’s Law, such as Papillon-Lefevre disease, Chediak-Higashi disease, hypophosphatasia, congenital and cyclic neutropenia, leukocyte adhesion deficiency, glycogen storage disease and Ehlers-Danlos disease. Mutation on Cathepsin C, lysosomal trafficking regulator, ALPL, ELANE, Beta-2 integrin chain, GDP-fucose transporter-1, SLC37A4 and Collagen alpha-1/2(V) genes are identified (Khoht & Albandor, 2014).

With such a profound genetic influence, these diseases often manifest in prepubescent and express early impact on the permanent and even primary teeth periodontium. It is not uncommon that some AgP cases have undetected or partial penetrant systemic conditions like Papillon-Lefevre disease (Hewitt et al., 2004).

2.2. Inheritability of Periodontal Disease: Family Aggregation and Twin Studies

“Periodontitis as a manifestation of systemic disease” is merely a subclass in the classification of periodontitis, while the majority of the periodontitis cases belong to CP, followed by AgP (Armitage, 1999). AgP used to be called “periodontosis, juvenile periodontitis, early onset periodontitis, or rapidly progressive periodontitis,” while CP is used to be called as “adult periodontitis.”

Although only AgP is characterized by familial aggregation, both periodontitis classes could present within families (Armitage, 2004). Family members of the patients with common noncommunicable diseases like periodontitis normally have a higher possibility to develop the disease concerned, as they are more likely to share the same genetic or environmental risk factors compared to the general population, more so if the genetic factor plays a key role in the etiology. A familial pattern of periodontitis was reported in twins and families for the first time in 1967 (Benjamin & Baer, 1967). A high occurrence of periodontal disease was found in the relatives of the patients with an “early onset” form of periodontitis (Butler, 1969; Hoffman, 1983; Beaty et al., 1987). The prevalence of moderate to severe periodontitis in the family of the proband ranged from 40-50% or even higher (Beaty et al., 1987; Boughman et al., 1992; Lopez, 1992).

All these family studies implied the possibilities of genetic background concerning periodontal disease. However, as mentioned earlier, familial aggregation of the disease may be the result of shared environment or genetic background, as both factors can contribute to progression of human periodontitis.

In the family-based studies above, some shared environmental factors are suggested to be one significant reason, such as transmission of periodontopathogens between family members (Vandervelden et al., 1993; Petit et al., 1994).

The proportion of the phenotypic variance determined by the genetic factors is referred to as the heritability of the disease concerned. In order to differentiate the genetic and environmental influences and to evaluate the heritability of periodontitis, twin studies were carried out until the late 1990s.

Theoretically, monozygotic twins share more similarities than dizygotic twins, while dizygotic twins are no more similar than normal siblings. Assuming the twins share the same environment, when periodontal disease occurs more often or more severely in monozygotic than dizygotic twins, it means that some genetic risk factors related to the disease may be in operation. In CP, the concordance rate of monozygotic twins experiencing periodontitis (0.23 to 0.38) is significantly higher than dizygotic twins (0.08 to 0.16) according to a self-reported twin study, which indicated that the similarity of disease experience is consistent with the genetic similarity (Corey et al., 1993). After adjustment of environmental and behavioral factors, similar results were repeated in other studies regarding both severity and extent of the disease. By comparing twins reared together and apart, a study with 110 pairs of adult twins estimated that heritability and, hence, genetic factors may contribute to 38~82% of the individual variance for periodontal status (Michalowicz et al., 1991). A heritability of 50% was reported in aggressive periodontitis as well. These early twin studies verified the genetic influence on periodontitis and provided some evidence of the disease heritability for future studies.

2.3. Heredity Mode and Heterogeneity: Segregation Analysis and Early Linkage Study

At the beginning, it was assumed that there was a major-effect gene for periodontal disease based on Mendel's law, so segregation studies and pedigree analysis were used to investigate its proposed inheritance modes. The first paper published in 1980, analyzing 129 first-degree relatives of 31 juvenile periodontitis or AgP probands, suggested an autosomal recessive model of inheritance (Saxen, 1980). This inheritance mode of periodontitis in Caucasians was advocated in some other studies (Fourel, 1972; Jorgenson et al., 1975; Beaty et al., 1987). In contrast, a study with more than 100 AgP families reported an autosomal-dominant transmission in both blacks and non-blacks, with a penetrance of 70% (Marazita et al., 1994). Besides autosomes, genders present an association with AgP as well. The excess of female proportion in the affected subjects was explained as an X-linked dominant form of AgP (Melnick et al., 1976; Page et al., 1985). It is surprising to see all these various hereditary modes suggested for periodontitis if the disease is considered to be passed on in a simple Mendelian fashion. The debates and conflicts on hereditary modes are actually caused by the wrong primary assumption. The heterogeneity of this complex disease could not be explained by one gene with major effect, so traditional approaches analyzing Mendelian diseases are not suitable for periodontitis. Moreover, neither twin studies nor these early segregation studies can locate the risk genes on the chromosomes.

In order to map the chromosomal location of disease-associated gene(s), linkage study protocols were adapted for periodontitis. They are based on the co-segregation of genetic markers and the disease-predisposing/-associating gene, because they are in physical proximity within the same chromosome and therefore have a high likelihood to pass on together in a pedigree. The genetic markers could be microsatellite, single nucleotide polymorphisms (SNPs) or a known disease-associated gene for another condition.

In 1986, a high co-occurrence of localized AgP and type III dentinogenesis imperfecta was reported in a family. A linkage analysis revealed that a known risk locus for the type III dentinogenesis imperfecta on chromosome 4q is closely linked with this localized AgP (Boughman et al., 1986). However, another study failed to verify this result, and chromosome 1 was suspected to be linked with AgP (Hart et al., 1993; Li et al., 2004). The controversies of all the early studies above forced people to reconsider the genetic nature of periodontitis and the genetic model of simple Mendelian inheritance regarding periodontitis was doubted. In fact all the results from previous studies suggested that the condition is influenced by complex multigenetic factors.

2.4. Complex Common Disease Associated with Single Nucleotide Polymorphisms

Since the previous studies have failed in identifying a major-effect risk gene, periodontitis is now realized to be a complex common disease. Based on the concept of "common disease common variances hypothesis," periodontitis should be influenced by multiple genetic polymorphisms. The hypothesis predicts that the genetic polymorphisms causing common disease should be frequent in the human population. Common diseases, such as periodontitis, hypertension and diabetes, are usually not immediately fatal at the early stage, so the allele

carriers can survive and possibly pass the genes to their offspring. Therefore, the frequencies of these genetic polymorphisms are stable in the population, and we refer to them as “common variance.” SNPs are the most common genetic variants. In periodontal diseases, especially CP, the effect of the each genetic variant is relatively small. Association study is a classical genetic method used to detect risk alleles with small to moderate effect in common diseases, while linkage study may not have enough power for this instance (Hodge, 1994; Cardon & Bell, 2001; Tabor et al., 2002).

2.4.1. Candidate Gene Association Study

Many studies adopted candidate gene association study in the last decades for periodontitis. In a candidate gene association study, the targeted locus is selected based on the current knowledge of the molecular etiology or plausibility for the disease. Genes regulating the pathogenic pathway are common candidates. The first paper of this kind concerning the periodontitis association study was published in 1997 and revealed the association between IL-1 polymorphisms and CP (Kornman et al., 1997). After that, hundreds of SNP association studies were done on periodontal disease. Candidate genes selected were mainly on the aspects of immuno-regulation or bone/collagen metabolism, such as genes encoding cytokines, cell surface receptors, chemokines and enzymes (Chai et al., 2012). The more intensively investigated polymorphisms of this sort are discussed as follows.

2.4.2. Cytokine

2.4.2.1. Interleukins (IL)

IL-1

IL-1 is an important inflammatory cytokine consisting of 13 subfamilies produced by monocytes, macrophages and dendritic cells. IL-1 α and IL-1 β are the two major subtypes, while the former mainly works as an intracellular regulator affecting the local inflammation and the latter is a released extracellular protein. A significant increase on the transcript levels of *IL1A*, *IL1B* and *IL1RN* genes was found in the gingival tissue of periodontitis patients (Braosi et al., 2012). The study on genetic polymorphism of *IL1* was one of the first SNP studies on periodontitis (Kornman et al., 1997). The polymorphism composition of IL-1 α -889 (rs1800587) and IL-1 β +3954 (rs1143634) was significantly associated with the severity of periodontitis in Caucasian nonsmokers with a reported high odds ratio of 18.9. After that, numerous studies were carried out on periodontitis and *IL1* polymorphisms, including IL-1 α -889/+4845 (rs1800587), IL-1 β +3953/4 (rs1143634), IL-1 β -511/-31 (rs16944) and IL1RN VNTR +2018 (rs2234677) (Laine et al., 2012).

A meta-analysis of 53 studies including 4178 cases and 4590 controls demonstrated a significant association of IL-1 α -889 and IL-1 β +3953/4 polymorphisms and a weak but positive association of IL-1 β -511 with CP but not AgP (Nikolopoulos et al., 2008). These two SNPs are verified to be associated with CP in Caucasians in a second meta-analysis (OR=1.48-1.54, MAF=0.22~0.28) (Karimbux et al., 2012), another systematic review also reported consistent and significant results of IL-1 α -889 in both Caucasians and Asians (Mao et al., 2013).

However, the frequencies of these SNPs are much lower in Asians (MAF of rs1800587=0.08~0.09 and MAF of rs1143634=0.02~0.04), though the systemic review above reported a positive result (Armitage et al., 2000; T. Kobayashi et al., 2009). A recent study in 2015 tried to ascribe it to the linkage disequilibrium between these SNPs with the functional SNPs. The working hypothesis was that these previously tagging alleles are variable among populations with different ethnic backgrounds but the true functional alleles will be consistent. By genotyping four SNPs in the *IL1B* promoter region (rs16944, rs1143623, rs1143633 and rs4848306), Caucasians, Africans, Hispanics and the Chinese population all presented a significant association with the IL-1 genes concerned (Wu et al., 2015).

IL-4 and IL-13

IL-4 is a cytokine, which triggers the differentiation of a naïve T cell to a T helper 2 cell and promotes the B lymphocyte-mediated immunity. Inflamed gingival tissues are enriched in macrophages but lack IL-4. Topical application of IL-4 increased the macrophage apoptosis in adult periodontitis and down-regulate CD14 expression in monocytes, a major receptor of lipopolysaccharides (LPS) from periodontopathogens (Shapira et al., 1992; Yamamoto et al., 1996).

Therefore, it was suggested that the absence of IL-4 contributes to periodontal tissue destruction. The low IL-4 concentrations in the gingival crevicular fluid (GCF) are also associated with periodontal disease progression (Kabashima et al., 1996; Tsai et al., 2007).

IL-13 is a cytokine that confers similar function on human monocytes as IL-4 (Yamazaki et al., 1997), which is not detectable in periodontitis lesions. The cytokine can activate TGF- β production in macrophages while acting directly or indirectly on fibroblasts, which activates collagen production and inhibits matrix metalloproteinase-3 synthesis in the latter, hence attenuating tissue destruction in periodontitis (Wynn, 2003; Fukuda et al., 2006).

Several studies have reported SNPs of IL-4 and IL-13 associated with periodontitis. In a recent study in the Chinese population, -590 variation of *IL4* was found to be significantly associated with CP (Loo et al., 2012). A correlation was found between IL-13 -1112 (rs1800925) and the susceptibility of AgP, with odd ratios ranging from 4.48 to 6.45 (Wu et al., 2010). All the SNPs studied were located in the promoter region of the genes concerned.

A recent meta-analysis summarized the association between periodontitis and IL-4 polymorphisms, namely -590 C/T (rs2243250), -33 C/T (rs2070874) and 70-bp polymorphisms. After analyzing 23 case-control studies (with 1,220 cases and 2,039 controls for -590 C/T, 715 cases and 967 controls for -33 C/T, 426 cases and 506 controls for 70-bp), the author concluded that IL-4 -590 T allele and TT genotype were significantly associated with an increased risk of periodontitis in whites but not in Asians (Yan et al., 2014). It may imply the SNP confers different influences on diverse ethnic groups, but the result should be interpreted with caution, as there was evidence indicating publication bias, which was mentioned as one of the study limitations by the authors.

IL-6

Produced by T cells, macrophages and even osteoclasts, IL-6 is an anti-inflammatory cytokine through its inhibitory effect on IL-1 and tumor necrosis factor- α (TNF- α). Salivary IL-6 showed a strong ability to predict an individual's likelihood to develop gingivitis (Lee et al., 2012). A few studies investigated the association between the genetic polymorphisms of IL-6 gene and periodontal disease. Multiple loci on the region of *IL6* were studied, including

IL-6 -174 (rs1800795), -190, -373, -572 (rs1800796), -597 (rs1800797), -1363 (rs2069827), -1480 and -6106 (Laine et al., 2012). A meta-analysis in 2013 accessed the association between periodontitis and two SNPs in the promoter region of the IL-6 gene. The review contained 16 studies on IL-6 -174 polymorphisms and 10 studies on IL-6 -572 polymorphisms and concluded that the significant result of -174 was detected only in the Brazilian population and that the polymorphisms on -572 may be associated with the increased risk of CP in Europeans (Song et al., 2013a).

IL-10

IL-10 is produced by both T cells and B cells. As a multi-functional cytokine, it can inhibit the expression of cytokines from T helper 1 cell, MHC class II antigens, and co-stimulatory molecules on macrophages. Meanwhile, it facilitates the differentiation, development and proliferation of B cells as well. A few loci of *IL10* have been reported to be associated with periodontal disease, such as polymorphisms on -1087/-1082(rs1800896), -627, -819/-824(rs1800871) and -592/-597(rs1800872) (Laine et al., 2012). Two meta-analyses, both published in 2012, presented the same observations, i.e., the polymorphisms of -819 and -592 of the IL-10 gene are associated with the susceptibility of periodontitis (Albuquerque et al., 2012; Zhong et al., 2012).

2.4.2.2. Tumor Necrosis Factor Alpha

TNF- α is a pro-inflammatory cytokine produced mainly by macrophages and a variety of other cells in the acute phase reaction to systemic or localized inflammation. The cytokine may induce the differentiation of osteoclast and contribute to bone resorption alongside IL-1 (Kobayashi et al., 2000; Loos et al., 2005). As an overreacted host response to the periodontopathogens, the increased local TNF- α leads to destruction of connective tissue and apoptosis of fibroblasts in the deeper part of gingival tissue (Graves & Cochran, 2003).

One SNP in the intron region (-489) and many in the promoter region [-238 (rs361525), -308 (rs1800629), -367, -857, -863 (rs1800630), -1031] of *TNFA* were investigated regarding their association with periodontitis (Laine et al., 2012). A recent meta-analysis studied the influence of TNF- α -308G/A, -863C/A and -238G/A polymorphisms on CP or AgP. The A allele at -308 and -863 was found to be associated with both kinds of periodontitis (Ding et al., 2014).

2.4.2.3. Cell Surface Receptors

The Fc Gamma Receptor Genes

The Fc γ receptor is a receptor protein on the surface of various cells, including B cells, dendritic cells, macrophages, neutrophil and natural killer cells. It specifically binds to the Fc part of the antibodies, such as IgG, and leads to phagocytosis and cytotoxicity of the IgG bound antigen/pathogen. There are nine subclasses in the family of Fc γ receptors (CD64: Fc γ RIa, Ib and Ic; CD32: Fc γ RIIa, IIb and IIc; CD16: Fc γ RIIIa and IIIb and Fc γ RIV). Strong IgG mediated responses to periodontopathogens in gingival tissue were observed along with Fc γ receptors commonly found in both gingival and pocket epithelium, indicating that the Fc γ receptor may play a crucial role in immune responses against bacteria causing periodontitis (Chai et al., 2012).

The polymorphisms of *FCGR1A*, *IIB*, *IIIA* and *IIIB* are investigated in both AgP and CP in various ethnic groups (Laine et al., 2012). A meta-analysis of 17 studies, consisting of 1685 cases and 1570 controls, investigated three SNPs, including *FcγRIIIa* H131R (rs1801274), *FcγRIIIa* F158V (rs396991) and *FcγRIIIb* NA1/NA2. Only the *FcγRIIIb* NA1/NA2 polymorphism presented a significant association with both kinds of periodontitis with the odds ratio ranging from 1.397 to 2.005 (Dimou et al., 2010). Many of the studies included in this review have a relatively small sample size. Our recent study on *Fcγ* receptor gene polymorphisms in 359 Hong Kong subjects reported that the C allele of rs445509 of *FCGR3A* provides a protective effect against chronic periodontitis, with an OR=0.3 after adjustment for age, gender and smoking (Chai et al., 2010).

Toll-Like Receptor

Toll-like receptors (TLR) are transmembrane proteins on host cells and play important roles in recognizing microbes or dangerous molecules. There are more than ten subclasses in the TLR family, of which TLR2 and TLR4 are the most extensively studied in periodontitis. The TLR4-dependant pathway can be activated by LPS of periodontopathic bacteria, like *Porphyromonas gingivalis* and *Capnocytophaga ochracea* (Yoshimura et al., 2002). The association between periodontitis and polymorphisms of *TLR2* and *TLR4* are investigated, including TLR2 Arg753Gln (rs57437087), Arg677Trp, Asp299Gly, Thr399Ile, -183, -148, -146, +1350 (rs3804100), +2343 and TLR4 Asp299Gly (rs4986790), Thr399Ile (rs498671), +3528, +3525, +4022, +4529. Three of these polymorphisms [TLR2 Arg753Gln (G2408A), TLR4 Asp299Gly (A896G) and Thr399Ile (C1196)] were investigated in a meta-analysis in 2013. After analyzing 14 studies, the author reported a lack of evidence regarding the association between these SNPs and periodontitis (Song et al., 2013b). However, an earlier meta-analysis in 2009 reported a different conclusion, that the TLR4 Asp299Gly allele A increases the risk of chronic periodontitis (OR=1.43, after analyzing seven studies), and the allele C of TLR4 Thr399Ile polymorphism shows a protective effect against aggressive periodontitis (OR=0.29, after analyzing four studies). The results were tested again using random effect models, which were more appropriate when the genetic heterogeneity was present. The significant result of TLR4 Asp299Gly was retained after the test, but TLR4 Thr399Ile was not (Ozturk & Vieira, 2009). The review in 2009 assessed the CP and AgP data separately, while the one in 2013 combined the two diseases. The inconsistency of these two reviews could be explained by the different individual studies included or by the fact that the TLR4 Asp299Gly is associated with CP but not AgP, so this polymorphism can present a positive result even in the analysis with a smaller sample size in the earlier review. Yet, more qualified studies with bigger sample sizes and a clear disease definition are required in the future.

Vitamin D Receptor

The Vitamin D receptor (VDR) is related to periodontitis based on the mechanism of the former influencing the bone mineral density, turnover and bone loss (Uitterlinden et al., 2006). Women with active or prior history of periodontitis have higher plasma vitamin D (25-hydroxyvitamin D-3) (Jabbar et al., 2011). There is a start codon polymorphism in *VDR*, consisting of three codons before a second start site (ATG). The corresponding genotype is determined by the restriction enzyme *FokI* and leads to some functional consequences in immune cells. This polymorphism has either a long form (f-VDR) or a shorter form (F-VDR)

protein. The difference between “f” and “F” is that the restriction site for *FokI* and the first ATG is present in f-VDR but is absent in the F-VDR. The presence of the shorter F-VDR results in higher NF-kappa B and NFAT-driven transcription, higher IL-12 p40 promoter-driven transcription and T lymphocytes with higher proliferation, which may therefore affect immune cell behavior and functions in immune-mediated diseases (van Etten et al., 2007).

Two meta-analyses were carried out but showed different results. The one published in 2011 summarized a total of 15 studies with 1338 cases and 1302 controls and assessed the SNPs of VDR *TaqI* (rs731236), VDR *BsmI* (rs1544410), VDR *FokI* (rs2228570) and VDR *Apal* (rs7975232). The latter analysis in 2012 included four more studies while focusing on the same SNPs. Both of the studies failed to detect any significant result in their overall analysis. However, in the subgroup of Asian subjects, the AA genotype of *Apal* was significantly associated with CP after Bonferreni’s correction for multiple comparisons in the first paper but not the second one. On the contrary, *TaqI* may decrease the risk of CP, and *FokI* presents a marginal protective effect against AgP under some genetic models in Asians (Deng et al., 2011; Chen et al., 2012). The difference may be caused by the unequal number of studies included, different inclusion and exclusion criteria, or diverse genetic models. The significant result in Asians but not Caucasians may be explained by the sample size, as there were twice as many Asian subjects as white subjects.

2.4.2.4. Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) degrade extracellular matrix (ECM) components in connective tissue, including that of human periodontium. There are more than twenty members in this family. Most of them, functioning as enzymes that degrade collagens, have been detected in periodontal tissue and are related to gingival inflammation (Ingman et al., 1996). MMPs’ expressions are higher in the pathogen-induced inflamed periodontal tissue than normal healthy tissue. Clinicians use chemical MMP inhibitors including doxycycline as adjuncts to periodontal mechanical therapy (Sorsa et al., 2006). The polymorphisms of MMP1, MMP2, MMP3, MMP9 and MMP12 genes have been studied in periodontitis subjects (Laine et al., 2012).

MMP1 is the most generally expressed MMP against fibrillar collagens (collagen types I, II, and III). A meta-analysis containing 11 studies with 1580 periodontitis cases and 1386 controls indicated MMP1-1607dupG polymorphism associated with increased disease susceptibility (Li et al., 2013). Published in the same year, a similar result was reported in another meta-analysis considering 10 studies, with 8 of them also included in the Li et al. (2013) meta-analysis. Additionally, the Song et al. (2013b) group reported a negative association between *MMP9* and CP (Song, Kim, et al., 2013). Polymorphisms of the *MMP3* gene were reported to be significantly associated with CP in individual case-control studies in various populations, but no meta-analysis so far has been carried out (Astolfi et al., 2006; Letra et al., 2012; Li et al., 2012). Nevertheless, neither Chinese AgP nor Japanese CP patients appeared to have their disease associated with *MMP3* SNPs (Itagaki et al., 2004; Chen et al., 2007).

2.4.2.5. Summary of Candidate Gene Study

Besides the genes discussed above, there are many other polymorphisms studied on periodontal disease (Kinane & Hart, 2003; Kauppila, 2009; Laine et al., 2012). These candidate gene studies portray a rough sketch regarding the landscape of periodontitis genetic studies and inspire future directions for periodontal research. However, inconsistent results from various

studies, including meta-analyses, reveal the problem that candidate gene association studies suffered from insufficient sample size and, hence, low power, ethnic heterogeneity, and diverse inclusion and exclusion criteria based on different or loose disease classifications (Kinane & Hart, 2003; Yoshie et al., 2007; Nikolopoulos et al., 2008; Noack et al., 2008; Dimou et al., 2010; Ryder, 2010).

Ambiguous phenotype classification and various attention levels applied to confounding factors, such as smoking status and age, increased the difficulty of, and at the same time reduced the reliability of, meta-analyses. Repeated low-quality studies with less than ideal study design, limited sample size or ill-defined underlying pathogenic mechanisms of some candidate genes selected all turned out to be of low intellectual value. A large-scale replication study containing more than two thousand Caucasians in an attempt to verify the relevance of 23 SNPs previously reported to be periodontitis associated revealed that the initial positive results repeated on most of the candidate gene association studies were due to type I error (Vaithilingam et al., 2014). A sample size with a minimum of 1,000 well-defined cases is suggested to be an indispensable prerequisite for identification of a risk allele with an odds ratio of more than 1.3. Obviously, most of the previous candidate gene studies regarding periodontitis are underpowered (Schäfer et al., 2011). Instead of a single locus, a complete set of all haplotypes of the candidate gene shall be analyzed to cover all the potential causal alleles. Otherwise, follow-up fine mapping needs to be performed to evaluate the SNPs within linkage. Detailed information of confounding factors should be recorded and adjusted, whereas standard phenotype classification of either CP or AgP should be utilized in the candidate association studies in the future.

2.4.3. Genome-Wide Association Study (GWAS)

Genome-wide association study (GWAS) is based on the HapMap project that revealed more than 10 million common SNPs in 6 populations. By comparing the whole-genome SNPs between controls and cases, which potentially display some particular trait for disease, GWAS could be used to identify the disease or trait-associated alleles. Since the first GWAS paper on age-related macular degeneration in 2005, there have been more than 2000 GWASs published, and data upon more than 15000 SNPs were reported up to 20/2/2015 (<https://www.genome.gov/26525384>).

In contrast to candidate gene directed association study, GWAS is non-hypothesis directed, which avoids the bias and risk when choosing candidate genes. The unified classification of cases and controls with a large sample size in a single study enhances the reliability of the study result. The first GWAS on periodontitis published in 2010 reported a risk locus for AgP in Caucasians (Schaefer et al., 2010). By comparing 283 cases and 972 controls, rs1537415 in the intron region of the GLT6D1 gene was identified as a risk locus (OR=1.59). It was successfully verified by the replication study with another 602 cases and 577 controls. GLT6D1 is named glycosyltransferase 6 domain containing 1, with the function uncharacterized hitherto. This association was replicated in a Sudanese population, and the study reported an odd ratio of 1.5 (Hashim et al., 2015). The polymorphism of rs1537415 may alter the affinity of GATA-3, which is a transcription factor mainly expressed in T helper cells. There is no clear linkage from GLT6D1 to periodontal disease so far, but the risk locus is shared with patients with cardiovascular disease, which may indicate the mutual physiological inflammatory background (Schaefer et al., 2009).

After Schaefer and coworkers, there are six GWAS papers published on periodontitis to date (Divaris et al., 2013; Teumer et al., 2013; Feng et al., 2014; Freitag-Wolf et al., 2014; Shaffer et al., 2014; Shimizu et al., 2015). Four of them were on CP, one on AgP and the other one was not defined. None of them detected any SNPs with significant association, except rs1537415 (Table 1). SNPs with a marginal *p* value were selected in these papers and reported as suggestive genes. Some of the suggestive genes may relate to periodontal inflammation and have been studied in the previous research, such as *LAMA2*, *HAS2*, *HAS2AS*, *CDH2*, *ESR1* and *NPY*. *LAMA2*, the laminin alpha 2, is an extracellular protein that functions as a major component in the basement membrane. Its expression is increased in inflamed periodontal ligaments (PDL) (Han & Amar, 2002). *HAS2* (hyaluronan synthase 2 gene) produces hyaluronan synthase 2, a membrane-bound enzyme that may facilitate tissue repair, promote proliferation of PDL cells and even inhibit pathogens (Rodrigues et al., 2010; Takeda et al., 2011). *CDH2* (gene of Cadherin-2, which is a calcium-dependent cell adhesion glycoprotein) and *ESR1* (estrogen receptor 1 gene) are both reported to be relevant for differentiation of PDL cells (Lin et al., 1999; Pan et al., 2011). *ESR1* is also involved in the regulation of bone modeling (Zhang et al., 2011). Neuropeptide Y (NPY) is highlighted in two of these GWAS papers, on both Caucasian CP and AgP individuals. NPY works as a neurotransmitter in the brain and in the human autonomic nervous system (Colmers & El Bahh, 2003). NPY Y1 receptors were detected in the gingival tissue, and a lower NPY protein level was found in human GCF from periodontitis patients (Lundy et al., 2009). It is abundant in bone and may help maintain homeostasis of the tissue. Concerning T helper type 1/2 cell balance, NPY also enhances the Th2 cell-mediated anti-inflammation response (Freitag-Wolf et al., 2014). Therefore, *NPY* could be considered an important gene related to periodontitis susceptibility and could warrant further investigation. However, there is limited evidence linking the rest of the genes suggested with periodontitis. On the other hand, functional studies are also essential to confirm the pathophysiological contributions of these potential risk-indicating genes.

So far, no significant association was identified from these GWASs except *GLT6D1* for AgP. It is probably because of the insufficient sample sizes of the currently available GWASs, which were not enough for small-effect SNP risk detection regarding the complex human disease of periodontitis. Meta-analysis should be performed by inputting different genotyping platforms, and it may assist in achieving a higher power and eventually a positive result if possible. More international cooperation is required to identify the genes of periodontal disease susceptibility across multiple ethnic groups.

Some limitations of GWAS should be noticed. A recent systematic review compared the cancer-associated genes found by GWAS and candidate gene methods. The study analyzed a database with research since 2000 and found GWAS reported 269 significantly cancer-associated genes, while candidate gene methods reported 349. Only 7.1% of the genes were found significantly associated with cancer in both methods and with similar effect sizes (Chang et al., 2014). Additionally, compared to the estimation by traditional genetic methods, like familial and twin studies, the heritability found by GWAS seems limited. For instance, like human height, the genetic factor is regarded as the main contributor because traditional genetic studies advocated a heritability of 80~90% regarding the phenotype.

However, according to three GWASs, the trait-associated single SNPs contribute only 5% of the height heritability. When such a phenomenon was translated into disease heritability, i.e., causation apparently proven by traditional genetic studies but which cannot be explained by GWAS, a new term “missing heritability” was defined (Maher, 2008). The missing heritability

may be caused by rare variants, structural variations, gene-environmental interactions, parent of origin effects, and errors in narrow-sense heritability estimates and epigenetics, which means the effected molecules may be modified by other factors on a transcriptional or translational level. One of the problems concerning GWAS is that as SNPs are defined as the common variation with the prevalence of more than 1%, it is difficult to detect an uncommon disease caused by rare disease alleles (Zaitlen & Kraft, 2012).

Table 1. Summary of Periodontitis GWAS

Author (year)	Periodontitis type	Initial Sample Size	Replication Sample Size	Reported Gene(s)	SNPs	Context	Risk Allele Frequency	p-Value*	OR	95% CI	Platform [SNPs; passing QC]	Functional study
Schaefer et al. 2010	Aggressive	283 German cases, 972 German controls	Dutch: 602 cases, 577 controls	GLTSD1	rs1537415	intron	0.38	6.0E-09*	1.59	[1.36-1.86]	Affymetrix [345,646]	Fine mapping and annotation

2.5. Future Direction

The lessons we learned from these earlier candidate gene studies and GWASs inspired us to consider improving our current study design, appreciate the genetic background of different periodontitis and stimulate exploration for the future research direction.

Case selection should be considered as a key or major issue in future study design. Cases with earlier onset and more severe clinical symptoms may reduce the phenotypic heterogeneity and increase the study power. According to the disease feature and previous genetic studies, we may assume that some of the periodontitis cases, such as some CP cases, may be mainly

influenced by the lifestyle (smoking, diet, stress) or the etiological factors (periodontopathogens), while certain AgP cases are determined by some rare genetic variances, and these rare genetic risk factors have a major effect on pathogenesis (Stabholz et al., 2010). Therefore, issues that have been argued for decades should be revisited again: Is the current disease classification suitable for periodontitis genetic study? Do CP and AgP exhibit fundamentally different genetic backgrounds concerning pathogenicity? In other terms, shall we establish a new classification based on the appreciation regarding different levels of genetic influence? How does that affect our current clinical diagnosis? In some AgP cases, the disease is affected by rare genetic variances, and association studies, either population-based candidate gene study or GWAS, do not have enough power for proper investigation. Family-based study design and large pedigree analysis should be utilized in this AgP category. Distant relatives are supposed to have less common alleles than close relatives. The disease status and the theoretical degree of genetic resemblance can be used to predict the locus of the disease-associated genes using linkage analysis, i.e., the “identity by descent” approach. As the next generation of sequencing develops, we are now capable of sequencing more genes not only limited to the SNPs concerned, with lower cost. Whole exome sequencing and even whole genome sequencing for every suspected locus becomes possible these days. Together with “identity by descent,” such approaches may give researchers a better chance to identify the genes for periodontitis susceptibility, especially for rare AgP. Additionally, because of the pleiotropy of some shared-risk genetic factors between the complex diseases, genes previously identified as susceptible genes for other systemic chronic inflammatory diseases, such as cardiovascular diseases, diabetes or even cancers, could be considered as candidate genes in future periodontitis studies (Vaithilingam et al., 2014).

3. FUNCTIONAL STUDY

Ideally, the allele of disease susceptibility would be located in the protein-coding region, so the disease mechanisms could be easily identified, provided that the function of the underlying molecule(s) of concern could be revealed. However, most of the loci that were found to be associated with periodontitis, similar to that of many other complex common diseases, were located in the non-coding region of the gene(s) concerned, such as the regulatory region. How to link these risk alleles to the pathogenesis and causality of periodontitis remained a major problem after the initial genetic screening/detection.

3.1. Observation at the mRNA and Protein Level

Observation at the mRNA and protein level of concern in the subjects with different genotypes is the initial step of the functional study on periodontitis. The differences in expression level of the genes could be tested directly from samples of saliva, serum, GCF or gingival tissue.

As the first SNPs ever studied in periodontitis, there are many functional studies testing the impact of the IL-1 polymorphisms on the disease concerned. The cytokine levels of IL-1 α , IL-1 β and TNF- α in the GCF of subjects with or without the particular IL-1 α +4845 and IL-1 β

+3953 polymorphisms were soon assessed after the first association study. The concentration of IL-1 β is higher in the patients with the periodontitis-associated genotype, and the difference sustained even after periodontal treatment (Engebretson et al., 1999). Another study reported the patients with T allele on the -889 of *IL1A* have increased IL-1 α level in the GCF by fourfold compared to controls (Shapira et al., 2005). The mRNA and protein levels of other genes were studied as well. Significantly more CP patients and individuals with higher *P. gingivalis* HmuY-induced IL-6 have the G allele at position -174 (Trindade et al., 2013). A study with 122 CP patients and 532 healthy controls assayed the serum levels of MMP-1, MMP-3, MMP-9, IL-2, IL-8 and COX-2 of their subjects using ELISA. Concentrations of all the cytokines followed were higher in the CP patients, but only the -1562 T allele of the MMP-9 gene was found to be associated with higher serum level of MMP-9 compared with CC homozygote (Li et al., 2012). Negative results regarding target genes' expression are not uncommon, even though the gene concern is significantly associated with periodontitis. Although an *IL8* haplotype appeared susceptible to CP [-251(T/A) (rs4073), +396(T/G) (rs2227307) and +781(C/T) (rs2227306)] and IL-8 concentration showed an association with the volume of GCF, *IL8* haplotype was not associated with IL-8 cytokine levels (Corbi et al., 2012). The insignificant results may be caused by many reasons, regardless of the potential type I error that could occur, as mentioned previously in SNP association studies. We can group the disease status, exclude the subjects with some systemic disease, and match the age and genders, but it is impossible to control other factors, which may compensate the effect of the risk loci. The samples are usually collected at one time point from various subjects, and the negative results may be due to epigenetic modification, expression variation by time or other genetic variances which influence the same target.

3.2. Annotation

As negative results on the expression of mRNA or protein are commonly seen in the samples directly collected from subjects with different genotypes, further annotation of the risk loci is required to reveal the function of the genetic polymorphisms *in vitro*.

Annotation means analysis and interpretation of the DNA sequence for the consequent biological significance and process. It consists of mainly two parts. One is structural annotation, which is the basic annotation to recognize the protein-coding gene, RNA gene and other functional elements, like regulatory elements concerning the region or gene of susceptibility. By comparing the sequence similarities with the known functional sequences, these elements, including exons and introns, could be identified manually or computationally by some sophisticated software algorithms. The second part of annotation is the functional annotation, which explains the biological function of the gene or the corresponding protein, the regulation mechanisms and the interaction with other molecules.

As the risk alleles are usually found in the regulatory region of the genes, it is essential to characterize the function of these loci. The gene expression can be regulated in many stages, like transcription initiation, elongation and mRNA processing, transport, translation and stability (Maston et al., 2006). Most of the regulation of the transcription occurred in the initiation stage. The genetic polymorphisms could be found in the region of any regulatory elements, such as enhancers, promoters, insulators and silencers.

Both *de novo* computational analysis and experimental laboratory work contribute to the structural and functional annotation of the periodontitis-associated genes. The putative protein product of the expression could be predicted *in silico* by searching for proteins with similar sequences.

3.2.1. Computational Annotation

By integrating the knowledge of these regulatory elements and the risk-associated SNPs, software algorithms and online databases based on the literature or studies of other species can be used to study the influence of the risk alleles identified, such as transcription factor binding and activity. For instance, in the first AgP GWAS, the G allele of rs1537415 in the regulatory region of *GLT6D1* was identified as a risk allele associated with AgP.

More than five hundred binding models of vertebrate transcription factors were obtained from the TRANSFAC database in order to find the transcription factor, which is most likely to be affected by this SNP. The TRANSFAC database focuses on eukaryotic transcriptional regulation. It contains data on transcription factors, the corresponding target genes and regulatory binding sites.

The transcription factor binding affinities were evaluated by the TRAP method instead of experimental binding data, which is a biophysical model based on the genome-wide binding data from yeast (Schaefer et al., 2010). The C to G exchange of rs1537415 reduced the predicted binding affinity of GATA-3 significantly, which was later verified experimentally by electrophoretic mobility shift analysis. Computational annotation can indicate the potential function of the genetic variance effectively and efficiently, but experimental verification is required afterward.

After a set of genes were identified by previous genetic studies like GWAS, pathway analysis could be carried out to map the genes concerned with certain pathways and therefore reveal the pathogenesis of the disease. In one of the GWASs on CP, although it did not find significantly disease-associated SNPs, it reported eleven ingenuity pathway analysis canonical signaling pathways were significantly enriched in the moderate and severe CP cases.

Most of these pathways are related to neurotransmitters and nervous signaling pathways, which indicate the potential pathogenesis of CP and a new research direction in the future (Rhodin et al., 2014).

3.2.2. Experimental Annotation

Experimentally testing on cell or tissue models can exclude confounding factors and could become a fundamental part of functional study in the post-SNPs era. By establishing a cell or tissue model with the wild/mutated genotype by bimolecular methods, studies that control the other variants could focus on investigating the underlying pathogenic effect of the target SNPs. The function of rs1800972 in the 5' untranslated region of the human β -defensin 1 gene, an antimicrobial peptide that may be related to periodontitis, was investigated in 2009. The study constructed a cell model with the transfected chloramphenicol acetyltransferase (CAT) reporter gene and the 5' untranslated region and found that the gene with G allele produced much more CAT protein compared to other haplotypes. The SNP concerned was indicated as a cis regulatory element effecting transcription or translation of Human β -defensin 1 (Kalus et al., 2009). Another study in 2012 reported that the G allele of rs11536889 in 3'-UTR of TLR4 suppressed the luciferase activity induced by LPS or IL-6 (Sato et al., 2012). However, there

are very limited studies available regarding either computational or experimental annotation on risk SNPs relevant to periodontitis.

3.3. Epigenetic Regulation of Gene Expression and Gene-Environment Interactions

The epigenetic process chemically modifies the DNA and the associated proteins, so the genes will be selectively activated or inhibited and the expression levels will be affected as well. DNA methylation and histone deacetylation are two of the most extensively investigated epigenetic alterations. Methylation adds a methyl group to adenine or cytosine DNA nucleotides within a CpG dinucleotide context typically, while histone deacetylase removes an acetyl group from the histone and leads to a tightly histone-wrapped DNA. Both of them block the binding of transcription factors and are associated with transcription silencing. There are studies on these two epigenetic modifications on periodontitis, but limited studies elucidate the effect of the epigenetic modifications upon periodontitis-associated SNPs.

The impact of DNA methylation and histone modifications was studied on IL-10, via comparing the IL-10 gene expression in subjects with different genotypes of IL-10 -1087. In the B cells stimulated with LPS, the increase of the DNA methylation of histone H3 and acetylation of histone H4 of the genotype GG cells appeared higher than that of the AA genotype cells. In the unstimulated cells, a larger increase of the acetylation and methylation of histone H3 was detected in GG than AA genotype cells, while acetylation of histone H4 appeared higher in AA genotype cells (Larsson et al., 2012).

Gene-environment interactions and epigenetics should also be considered in the future. Gene-environment interaction in chronic inflammatory disease includes intrinsic and extrinsic mechanisms (Renz et al., 2011). Regarding intrinsic mechanisms, epigenetic variables link the disease phenotype and environment with the human genome in the disease. Environmental triggers like smoking may lead to epigenetic changes. The interaction between Vitamin D receptor gene polymorphism and smoking presented some evidence of association upon the severe periodontitis progression (Nibali et al., 2008a). Significant additive interaction shows the effect of VDR risk allele and smoking upon periodontitis appeared more than the effect of the sum of these two risk factors working separately (Tanaka et al., 2013). Concerning extrinsic mechanisms, periodontopathogens, for instance, could be regarded as a main factor. As oral microbiota is the cause for the inflammation in gingivitis or periodontitis, the prevalence of some key oral pathogens like *Aggregatibacter actinomycetemcomitans*, *P. gingivalis* and *Tannerella forsythensis* was found to be associated with IL-6 and Fcγ receptor gene polymorphisms (Nibali et al., 2007 & 2008b). The mutual interaction between host genetic factors and the pathogens has not been thoroughly investigated. With the development of next-generation sequencing, the relationship between human genome-wide information and the pathogen profile could also be a new study direction. A GWAS published in 2012 concerning 1020 Caucasians reported a negative association between the human whole genome SNPs and eight periodontopathogens detectable by DNA-DNA hybridization (Divaris et al., 2012). A larger sample size and perhaps more pathogens should be investigated in future studies.

CONCLUSION AND FUTURE DIRECTION

It has been proven that SNPs on various genes, such as IL-1, IL-6 and MMP-9 genes, confer influence regarding the corresponding gene's expression. Individuals with various genotypes associated with the corresponding mRNA and protein levels confirmed the potential effects of many SNPs on periodontitis. Whole exome sequencing and even whole genome sequencing become possible to detect rare variants with a relatively large effect. In order to elaborate particular periodontal pathogenic mechanisms, more computational or experimental annotations and epigenetic investigations should be performed in the future. Cell, tissue or even animal models with the normal/risk genotypes should be established to test the function and pathophysiology of the periodontitis-associated SNPs in order to decipher the mechanism of the disease development with all other factors controlled. Epigenetic modifications on the genes of interest by environmental factors, e.g., by a particular periodontopathogen or smoking, should also be characterized. Periodontitis is a dynamic and complex disease whose etiology cannot be explained or predicted by any known risk indicators. Inspired by the concept of "systems biology," multiple etiological and/or risk factors of the complex disease periodontitis could be integrated into a network and be regarded as one system with emergent properties, based on the complicated interaction among the factors included. By establishing a new model with more comprehensive information on the genomic, transcriptomic, proteomic and metabolomic levels, the environment and their interactions, people may stand a better chance of understanding periodontitis in the future.

Chapter 32

GENOMIC IMPRINTING AND THE BRAIN: NEURON-SPECIFIC SWITCHING OF GENE EXPRESSION AT IMPRINTING REGIONS

Masamitsu Eitoku and Hidenori Kiyosawa*

Department of Environmental Medicine, Kochi Medical School,
Kochi University, Nankoku, Kochi, Japan

ABSTRACT

Imprinted regions of the mammalian genome are commonly composed of one or more paired paternally and maternally imprinted genes and differentially methylated regions (DMRs). These DMRs are methylated in an allele-specific manner during germ-line or early embryonic development, and they regulate allele-specific gene expression. Although genes in most imprinted regions are expressed ubiquitously among tissues, some imprinted regions manifest tissue-specific gene expression patterns. The brain is a major site of tissue-specific gene expression from imprinted regions in embryonic tissues.

We summarize several imprinted regions that show neuron-specific gene expression patterns. First, we describe the *SNRPN-UBE3A* domain, which contains three brain-specific imprinted genes, *SNORD115*, *UBE3A-ATS* and *UBE3A*, as well as one imprinted gene with a brain-specific promoter, *SNRPN*. Second, we discuss the *DLK1-DIO3* domain, which contains the brain-dominant imprinted genes *SNORD112*, *SNORD113* and *SNORD114* as well as numerous brain-specific imprinted miRNAs. Third, we provide an overview of *Grb10*, which also has a brain-specific promoter and switches the imprinted allele during early neurogenesis.

Our chapter reviews these imprinted regions and describes the similarities and differences of the neuron-specific imprinting switch in each region.

INTRODUCTION

Genomic imprinting is an intriguing epigenetic phenomenon leading to allele-specific or allele-biased gene expression. Among the estimated 25,000 mammalian genes, a few hundred are imprinted, and some of these are clustered into restricted genomic regions [1]. Most but not all of these genes are regulated by differentially methylated regions (DMRs) within the cluster. This expression system is allele-specific and plays an essential role in embryogenesis. Mammalian reproduction requires both sexes as donors of gametes; the gametes from each parent, sperm and oocyte, function as vectors to transmit the imprinting marks, the pattern of methylation, from the paternal and maternal genomes to the embryo. The DMR is modified in two steps to enable the inheritance of these imprinting marks, which are maintained in somatic cells. The first step is erasure of the methylation of the DMR during the development of primordial germinal cells. The second step is the establishment of DMRs during gametogenesis in a sex-specific manner, resulting in different imprinting patterns in oocytes and sperm. The DMRs of the gametes are maintained and shared among the somatic cells that arise from them; however, tissue-specific genomic imprinting can also occur. Most of the tissue-specific imprinted genes are imprinted in extra-embryonic tissues such as placenta and yolk sac, but several neuron-specific imprinted genes have been reported. In this chapter, we provide an overview of representative imprinted regions that contain imprinted genes with neuron-specific expression patterns, focusing on the mechanism of the neuron-specific imprinting switch.

Overview of the *SNRPN-UBE3A* Domain

The imprinted domain *SNRPN-UBE3A*, located on human 15q11-q13 and mouse 7qC [2, 3], consists of two imprinted regions (Figure 1A, B). The first region contains several paternally expressed genes (*makorin/ring finger protein 3* [*MKRN3/ZNF127*], *MAGE-like 2* [*MAGEL2*], *Necdin* [*NDN*], *small nuclear ribonucleoprotein polypeptide N* [*SNRPN*], *imprinted in Prader-Willi syndrome* [*IPW*], several small nucleolar RNA [snoRNA] genes including *SNORD116/HBII-85* [*SNORD116*] and *SNORD115/HBII-52* [*SNORD115*] and the long non-coding RNA *UBE3A antisense* [*UBE3A-ATS*]). The second region contains a maternally expressed gene, *UBE3A* [4]. In both human and mouse, this domain contains at least three brain-specific imprinted genes, paternal *SNORD115* [5-7] and *UBE3A-ATS* [8, 9] and maternal *UBE3A* [10-12], and one gene with a brain-specific promoter, *SNRPN* [13-16]. This *SNRPN-UBE3A* domain is also a critical region for two neurobehavioral disorders, Angelman syndrome (AS) and Prader-Willi syndrome (PWS). The genes responsible for AS and PWS are *UBE3A* and *SNORD116*, respectively [17-21].

Igf2r, *Igf2* and *H19* were identified as the first three imprinted genes in mouse in 1991 [22-25]; *SNRPN*, which was the fourth to be identified [26], expresses a bicistronic transcript containing 10 exons. Exons 1-3 code for the protein “SNRPN upstream reading frame” (SNURF), and exons 4-10 code for the polypeptide protein “small nuclear ribonucleoprotein” (SmN) [27-34]. Although the exon 1 promoter drives expression of *SNRPN* ubiquitously, there are multiple untranslated upstream exons called U exons [13]. U1B and U1A function as brain-specific paternal promoters [13, 14], and U5 and U6 as oocyte-specific maternal promoters [35]. In both of brain-specific and oocyte-specific U exon-containing transcripts, U exons skip

exon 1 and splice into exon 2. The U exons also share sequence similarity, suggesting that they arose from genomic duplication [14].

The imprinting center (IC) in this locus is a bipartite IC composed of the shortest regions of deletion overlaps in AS patients (designated AS-SRO) and PWS patients (designated PWS-SRO), and it controls all imprinting of the *SNRPN-UBE3A* domain [13, 30, 36-40]. PWS-SRO, which spans exon 1, is also thought to regulate the expression of a large transcription unit that spans a genomic region of more than 460 kb and contains at least 148 exons, including those of *SNRPN*, *IPW* and *UBE3A-ATS* [41]. This transcript is alternatively spliced and serves as the host for the six intronic C/D box snoRNA species. Two of these species, *SNORD116* and *SNORD115*, are present in tandemly repeated clusters containing 29 and 48 gene copies, respectively [42].

Figure 1. (Continued).

Figure 1. Overview of the *SNRPN-UBE3A* domain. (A, B) Schematic representation of the human *SNRPN-UBE3A* domain in (A) brain and (B) non-brain tissues. Paternally expressed non-coding RNAs, including alternative U exon transcripts, *SNRPN*, snoRNA host gene transcripts (*116HG* and *115HG*), *IPW* and *UBE3A-ATS*, form part of a large transcription unit. The paternal *UBE3A* expression in brain is down-regulated by the neuron-specific paternal *UBE3A-ATS* transcripts driven from the U exons or exon 1, and the shortened *UBE3A-ATS* that possibly starts from a transcription start site (TSS) near *SNORD115*. U exons, *Snord116*, *Snord115* and *Ube3a-ATS* RNAs localize to their transcription sites. *SNRPN*, *116HG* and *IPW* transcripts are found in many tissues. In this and all subsequent figures, maternally and paternally inherited chromosomes are indicated as Mat and Pat, respectively, and figures are not drawn to scale. Genes and U exons are symbolized as rectangles and vertical bars, respectively. The orientation of transcription is shown by arrows. The alleles exhibiting maternal and paternal imprinted expression patterns are depicted in dark gray and light gray, respectively, whereas silenced alleles are depicted in black. Tandemly repeated snoRNA gene clusters contain intron-encoded snoRNAs (triangles) and nuclear-retained host genes (framed rectangles), which accumulate near their transcription sites. Methyated and unmethylated DMRs are indicated as lollipops with black and white circles, respectively. The black bar above the map indicates the location of the DNA FISH probe utilized to show the neuron-specific chromatin decondensation of the active paternal allele. (C) Schematic representation of the *SNRPN-UBE3A* domain of AS patients with maternal transmission of the AS-SRO deletion (white triangle). *UBE3A*, the gene responsible for AS, is not expressed. (D) Schematic representation of the *SNRPN-UBE3A* domain of PWS patients with paternal transmission of the PWS-SRO deletion (white triangle). *SNORD116*, the gene responsible for PWS, is not expressed.

Three of the snoRNA species, *SNORD64/HBII-13* (*SNORD64*), *SNORD107/HBII-436* (*SNORD107*) and *SNORD108/HBII-437* (*SNORD108*), are present as single-copy genes, and the last one, *SNORD109A/HBII-438A* (*SNORD109A*) and *SNORD109B/HBII-438B* (*SNORD109B*) [5, 41, 43, 44], is a double copy gene. *SNORD116* is ubiquitously expressed in substantial amounts, but is expressed at much higher levels in brain [5-7, 42]. *SNORD115* is also expressed primarily in brain [5-7] and modestly in kidney, liver, skeletal muscle and thyroid [42].

UBE3A-ATS is expressed exclusively in brain from the paternal allele [8]. In contrast, *UBE3A* is expressed biallelically in most tissues, but is only expressed from the maternal chromosome in various parts of the brain [11, 12]. Imprinting of *UBE3A* is not associated with

DMRs [45, 46], but the reciprocal expression of *UBE3A-ATS*, which overlaps with at least the 3' half of *UBE3A* and possibly with most of the gene body in humans, is thought to play a role in silencing the paternal *UBE3A* in brain [8, 41, 47].

Bipartite IC of the *SNRPN-UBE3A* Domain

Studies of the first reported human imprinting disorders, AS and PWS, provided evidence on the *cis* elements regulating allele-specific expression [4, 13, 30]. Mapping of micro-deletions of chromosome 15q11-q13 in families of AS and PWS patients identified AS-SRO and PWS-SRO (Figure 1C, D).

AS-SRO is an 880-bp region located 35 kb upstream of *SNRPN* exon 1 [37]. It contains an upstream, oocyte-specific promoter [35] and U exons U5 and U6 of *SNRPN*, which are present in a very small fraction of *SNRPN* splice variants [4, 14, 48]. In contrast, U exon-containing transcripts in oocytes start from these exons but do not include exon 1, which contains the major transcription start sites (TSSs) in brain. U exon-containing transcripts that initiate at U1B or U1A [14], the other common TSSs in brain, are also absent in oocytes, suggesting that *SNRPN* transcription has nearly reciprocal patterns of initiation on the paternal allele in brain and on the maternal allele in oocytes (Figure 2) [35].

PWS-SRO is a 4.1-kb region that includes the paternal allele-specific *SNRPN* promoter and exon 1. Although the maternal and paternal copies of PWS-SRO are, respectively, methylated and unmethylated [31], abnormally methylated paternal PWS-SRO silences the paternal-specific expression of *MKRN3/ZNF127*, *SNRPN* and *IPW* [36, 49]. The unmethylated (active) paternal *SNRPN* promoter is enriched with active histone marks (panacetylated H3, H4 and H3K4me), and the methylated (repressed) maternal *SNRPN* promoter is enriched with repressive histone marks (H3K9me) [50-52].

Developmental Regulation of the Bipartite IC

A series of analyses in mouse elucidated how these *cis* elements mutually interact and regulate one another during development [53]. Transgenic F0 mice that bear an exogenous transgene fragment containing human AS-SRO and PWS-SRO were created [54]. This exogenous fragment transmitted from the male or female F0 founder to their F1 offspring mimicked the imprinting patterns of DNA methylation and gene expression in endogenous paternal or maternal alleles, respectively. This system allowed the establishment and maintenance of differential methylation of AS-SRO and PWS-SRO to be studied in the gamete and especially in the embryo.

AS-SRO is methylated during spermatogenesis but not oogenesis, resulting in its acquisition of the paternally methylated pattern (Figure 2) [54]. This differential methylation is maintained through implantation but is not seen in the adult, consistent with the biallelic DNA methylation pattern in AS-SRO seen in human somatic cells [55, 56]. In contrast, the methylation of PWS-SRO, which has the maternally methylated pattern in somatic cells [31], takes place at the post-implantation stage [54], consistent with the absence of PWS-SRO methylation in human gametes [39].

Figure 2. Model for the establishment of brain-specific imprinting at the *SNRPN-UBE3A* domain, derived from human and mouse experiments. Schematic diagrams of the locus near *SNRPN* at various stages of development. Imprinting marks are erased in primordial germ cells, and the U exon transcripts are not expressed. In growing oocytes, U exon transcription is initiated from the oocyte-specific U exons in AS-SRO. Methylated paternal AS-SRO inherited by sperm is maintained through the post-implantation stage but is not seen in adults. Methylation of maternal PWS-SRO/PWS-IC occurs in the post-implantation stage in humans and in growing oocytes in mice. In mice, U exon transcripts themselves may contribute to this methylation and further maternal silencing. Unmethylated paternal PWS-IC is needed for brain-specific paternal expression of U exon-containing transcripts. Biallelic and monoallelic expression of mouse *Snrpn* is observed during gametogenesis and post-fertilization development, respectively. The AS-SRO and PWS-SRO are depicted as ovals overlying U exons 5/6 and *SNRPN* exon 1, respectively. In both of the brain-specific and oocyte-specific U exon-containing transcripts, U exons skip exon 1 and splice into exon 2. Exons of *SNRPN*, snoRNAs of *SNORD116* and *IPW* are symbolized as vertical bars, triangles and rectangles, respectively. The genes and exons exhibiting maternal and paternal imprinted expression patterns are depicted in dark gray and light gray, respectively, whereas silenced alleles are depicted in black. Transcription is shown by arrows. Methylated and unmethylated SROs are indicated as lollipops with black and white circles, respectively. Wide arrows show transitions between developmental stages.

AS-SRO is necessary for the establishment, but not for the maintenance, of PWS-SRO methylation [54]: a transgenic mouse with an exogenous transgene fragment containing human PWS-SRO and AS-SRO flanked by lox sequences was mated with a Cre-expressing mouse to remove AS-SRO; maternally transferred PWS-SRO was unmethylated when AS-SRO was removed prior to gametogenesis and methylated when it was removed after fertilization. A genetic analysis of AS and PWS families produced the same result, and also showed that PWS-SRO is not necessary for the establishment of AS-SRO methylation [56]. These results suggest that the primary, but temporary, imprinting occurs on AS-SRO during gametogenesis (gDMR) and causes allele-specific repression of the maternal PWS-SRO, resulting in the establishment of the secondary, and permanent, imprinting of PWS-SRO during post-fertilization development (sDMR).

The Role of U Exon Transcription in Maternal Silencing of *Snrpn*

Studies of other transgenic mouse lines demonstrated that transcription from the *Snrpn* U exons (U exon transcription) regulates the maternal imprinting at the PWS-IC [57], the region homologous to PWS-SRO in mouse [15, 36, 58, 59]. Although there is no mouse region homologous to the human AS-SRO, an AS-IC was identified as its functional equivalent in a series of knockout and transgenic mice, suggesting that humans and mice share a similar mechanism for establishing genomic imprinting with bipartite elements in this region [57, 60–62].

Two different transgenic mouse lines carrying the same single copy of a modified BAC transgene in different loci exhibited different imprinting patterns [57]. In the *Snrpn* upstream region, there are nine U exons lacking splice acceptor signals and five additional exons containing splice acceptor signals; all 14 exons contain splice donor signals. This BAC transgene contains *Snrpn* and 100 kb of upstream sequence spanning three of the U exons, all of which are deleted in this construct, and three of the additional exons. One transgenic mouse line lacked U exon-containing transcripts in the ovary, resulting in an imprinting defect, biparental *Snrpn* expression and DNA hypomethylation at the PWS-IC. The other line expressed an aberrant transcript containing an additional upstream exon in the ovary and displayed appropriate maternal silencing. These results suggest that U exon transcription through the PWS-IC is essential for AS-IC activity (Figure 2). In human, an AS patient had a point mutation in the splice donor site of U2, located upstream of the oocyte-specific promoter U5, suggesting that the U exon-containing transcript itself and not the process of transcription from the upstream promoter is important for the establishment of maternal silencing [13, 14].

The timing with which maternal silencing is established in the wild-type mouse also supports this idea (Figure 2). Demethylation of the PWS-IC occurs in the primordial germinal cells between 10.5 to 12.5 days postcoitus (dpc), resulting in biallelic expression of *Snrpn* [63–65]. While this biallelic expression pattern of *Snrpn* is maintained in both oocytes and spermatogenic cells, monoallelic expression of *Snrpn* is observed in each blastomere at the 4-cell stage [63, 66]. The U exon-containing transcripts are undetectable in 13.5 dpc primordial germ cells but become evident after birth [57]. Because the PWS-IC is first methylated in growing oocytes between 5 and 25 days postpartum (dpp) in a size-dependent-manner [67, 68], PWS-IC methylation occurs in the presence of U exon-containing transcripts.

A smaller (4.8 kb) deletion of the maternal PWS-IC resulted in a maternal imprinting defect that was accompanied by the expression of paternally expressed genes, such as *Snrpn*, *Snord116* and *Snord115*, from the maternal allele [69]. Brains from mice with a maternal PWS-IC knockout exhibited increased amounts of the maternal U exon-containing transcript that is silenced in the wild-type mouse, suggesting that the PWS-IC is also required for maternal imprinting. Thus, maternal methylation of the PWS-IC, which is mediated by AS-IC in oocytes, has a role not only in maintaining the silencing of ubiquitous *Snrpn* transcription that initiates from the exon 1 promoter, but also in down-regulating maternal U exon transcription that initiates from the oocyte-specific promoter U5, resulting in the ubiquitous maternal expression of *Ube3a* (Figure 2).

Regulation of Paternal Expression of *Ube3a-ATS*

A study of murine embryonic carcinoma cells (ECCs) provided evidence of the correlation between U exon transcription and *Ube3a-ATS* expression on the paternal allele in neuron [16]. Although *Snrpn* was expressed consistently during the time course of ECC neural differentiation, several U exon-containing transcripts and *Ipw/Ube3a-ATS* were up-regulated synchronously. Consistent with this result, detailed expression analyses of U exon-containing transcripts and *Ube3a-ATS* in mouse revealed an overlap in their tissue-specific and developmental expression [70]. Additionally, a knockout mouse with a 35-kb deletion, including a 16-kb upstream region containing the PWS-IC and six exons of the *Snrpn* gene, exhibited loss of paternal expression of the U exon-containing transcript and *Ube3a-ATS* and gain of paternal expression of *Ube3a* [9, 16].

Three additional mouse models with PWS-IC deletions distinguished the elements of the exon 1 promoter and the PWS-IC functional region. The 0.9-kb deletion did not affect the expression of U exon-containing transcripts despite a severe reduction in *Snrpn* transcripts [15, 71]. The 4.8-kb deletion of the paternal PWS-IC caused a partial defect of paternal imprinting of the *Ndn* locus and resulted in decreased expression of the paternal U exon-containing transcript and an increase of paternal *Ube3a* expression in brain, suggesting that the unmethylated paternal PWS-IC activates brain-specific U exon transcription (Figure 2) [69, 71]. The 6-kb deletion, which extended 1 kb further upstream of the 4.8-kb deletion, exhibited results similar to those obtained with the 35-kb PWS-IC deletion [59], including undetectable expression of paternal-only genes such as *Mkx3/Zfp127*, *Magel2* and *Ndn* as well as increased DNA methylation at the *Mkx3/Zfp127* and *Ndn* loci [72]. These results suggest the following two conclusions: (1) elements lying within the 0.9-kb PWS-IC deletion function as an exon 1 promoter to regulate ubiquitous *Snrpn* expression, and (2) elements lying within the 6-kb deletion but outside the 0.9-kb deletion are required for the PWS-IC to establish brain-specific paternal expression of the U exon-containing transcripts.

These two paternal transcripts, U exon-containing transcript and *Ube3a-ATS*, are expressed in neurons (but not glia) derived from primary cortical cultures [73, 74]; they are also linked on cDNAs derived from mouse brain, supporting the regulation of *Ube3a-ATS* expression by U exons [16]. Strand-specific RT-PCR of the region around *Ube3a-ATS* that overlaps the *Ube3a* 3'-UTR identified several transcripts containing some exons of *Ipw* and a part of *Ube3a-ATS* that overlaps with the *Ube3a* 3' end. Additional RT-PCR analysis of the region between *Snrpn* U1 and *Ipw* identified a short transcript that excludes *Snrpn*. These

results suggest that *Ube3a*-ATS expression is driven from brain-specific paternal *Snrpn* U exons and extends over a 1000-kb genomic region (Figure 1A). In expression analyses, *Ube3a*-ATS was reduced by 50% in mice with the 0.9-kb deletion of *Snrpn* exon 1, implying that mouse *Ube3a*-ATS is also transcribed from the *Snrpn* major promoter as it is in humans and that these two forms of the transcripts, *Ube3a*-ATS driven from U exons and exon 1, are expressed at the same level [71].

However, a recent CAGE-seq analysis in human libraries provided evidence of the existence of TSSs between the *SNORD116* and *SNORD115* gene clusters and within the *SNORD115* gene array, suggesting that transcription could also be initiated in the middle of the *SNRPN/UBE3A*-ATS transcription unit [42], producing a shortened *UBE3A*-ATS. Derivation and characterization of human induced pluripotent stem cells (iPSCs) from a PWS patient revealed that the region between *SNRPN* and *SNORD116* plays a role in the silencing of transcripts spanning *SNORD115* and *UBE3A*-ATS in non-neuronal cells and unsilencing them in neurons [75]. iPSCs with a small deletion spanning *SNRPN*, the *SNORD116* cluster and *IPW* expressed paternal *UBE3A*-ATS and silenced paternal *UBE3A* like neurons. The brain-specific U exon-containing transcripts, however, were not expressed in these iPSCs but were normally expressed in neurons differentiated from the same iPSCs, suggesting that the paternal *UBE3A*-ATS expressed in this iPSCs from a PWS patient is a shortened one driven from TSSs near *SNORD115* and neuron-specific paternal *UBE3A* silencing requires only paternal shortened *UBE3A*-ATS expression and no other neuron-specific factors (Figure 1A).

Neuron-Specific Chromatin Decondensation and Localization of Paternal Transcripts to Their Transcription Sites

Combined RNA and DNA fluorescent *in situ* hybridization (FISH) analysis revealed that *Ube3a*-ATS localizes to its transcription site in the nucleus (Figure 1A) [76], suggesting that it down-regulates *Ube3a* expression by forming a complex chromatin structure despite its short half-life of 4 h [71]. DNA FISH analyses revealed that the chromatin structure of the paternal *Snrpn-Ube3a* domain is decondensed and transcriptionally regulated in a neuron-specific manner through the PWS-IC (Figure 1A) [77, 78]. This decondensation occurs within the first 2 weeks after birth, prior to accumulation of *Snord116* in the nucleolus, and is required for increased nucleolar size during neuronal maturation. A combined RNA/DNA FISH analysis also revealed that *Snord116* and *Snord115* transcripts are processed into multiple snoRNAs from introns and into spliced, nuclear-retained host genes (*116HG* and *115HG*) from exons (Figure 1A). These *116HG* and *115HG*, which are repeated-exon-containing mRNA-like transcripts, also accumulate near their transcription sites, juxtaposed to U exon transcripts on the decondensed paternal genome [79, 80].

Combined immunofluorescence of the *Snrpn-Ube3a* domain with the S9.6 antibody, a DNA:RNA-specific antibody, and DNA FISH revealed that the decondensed paternal allele in the *Snrpn-Ube3a* domain overlaps with the DNA:RNA hybrid in adult mouse cerebellum [78]. Although the results of extensive RNase A treatment suggested that the chromatin decondensation might be caused by DNA:DNA rather than DNA:RNA hybridization [77], these results of FISH and immunofluorescence analyses suggest that some or all of the neuron-specific paternal genes, including the U exons, *Snord116*, *Snord115* and *Ube3a*-ATS, would localize to the transcription sites of these genes and form DNA:RNA hybrids.

The *Snord116* region was shown to form DNA:RNA hybrids called R loops *in vitro* and *in vivo* [78-80]. This region is required for topotecan-mediated chromatin decondensation at the *Snrpn-Ube3a* domain and for *Ube3a* silencing in cultured murine neurons, consistent with the human result indicating that topotecan treatment is less effective in repressing the *UBE3A-ATS* in PWS patient-derived iPSCs with a small deletion of the *SNORD116* cluster [78]. Topotecan, a topoisomerase I inhibitor, was found as a novel drug that reduces *Ube3a-ATS* expression by forming supercoils in front of the elongating RNA polymerase and unsilencing paternal *Ube3a* in mouse neurons [81]. Topotecan treatment also stabilizes increased R-loop formation at *Snord116* [78]. Because R loops impair transcription elongation [82-84] and the deletion of *Snord116/SNORD116* gene results in increasing of *Ube3a-ATS/UBE3A-ATS* in mice and humans [75, 78], R-loop formation in the *Snord116* cluster may be involved in the regulation of the paternal *Ube3a-ATS* expression.

Model of Paternal *Ube3a* Silencing by *Ube3a-ATS* Transcripts

Although RT-PCR analyses identified *Ube3a-ATS* transcripts overlapping the middle of the gene body and the 3'-UTR of *Ube3a* [9, 16], an single nucleotide polymorphism (SNP) array analysis and strand-specific microarray revealed that brain-specific *Ube3a-ATS* possibly terminates in the region 40 kb upstream of the *Ube3a* TSS, suggesting that *Ube3a-ATS* is actively transcribed at the *Ube3a* promoter (Figure 1A) [71, 85]. The amount of *Ube3a-ATS* transcripts decreased significantly in the middle of the locus toward the transcription termination site [71]. This is approximately the same region where the biallelic expression of *Ube3a* pre-mRNA is observed [76, 85]. These results support the transcriptional collision hypothesis, in which the two opposing polymerases II transcribing *Ube3a* and *Ube3a-ATS* on the paternal chromosome collide with each other and drop off of the template, thereby aborting transcription of both [71]. Results from the truncation of *Ube3a-ATS* also supported this hypothesis. A transcriptional termination cassette inserted downstream of *Ube3a* on the paternal chromosome reduced *Ube3a-ATS* transcription and unsilenced *Ube3a* expression *in vitro* and *in vivo* [71, 76]. This transcriptional termination cassette also suppressed the behavioral defects of an AS model mouse [76].

However, specific elimination of *Ube3a-ATS* transcripts with antisense oligonucleotides (ASOs) clarified that the transcripts of *Ube3a-ATS*, and not transcription per se, carry out neuron-specific paternal *Ube3a* silencing *in vitro* and *in vivo* [86]. ASOs, which are chemically modified DNAs of ~20 bp in length, penetrate into the nucleus and specifically hybridize with the target RNA. The RNA in the ASO-RNA heteroduplex is cleaved by RNase H and subsequently degraded by exonucleases without inhibiting transcription. Treatment with an ASO, that contained the sequence of the downstream region of the *Ube3a* gene to target *Ube3a-ATS*, reduced paternal expression of *Ube3a-ATS* and unsilenced paternal *Ube3a* in the brain (especially the cortex and hippocampus) and spinal cord. Because *Ube3a-ATS* transcripts span the *Ube3a* promoter and localize to its transcription site [71, 76, 85], *Ube3a-ATS* transcripts may cover *Ube3a* promoter and block the access of RNA polymerase II (Figure 1A).

Overview of the *DLK1-DIO3* Domain

The imprinted *DLK1-DIO3* domain is located in the human 14q32 and mouse 12qF1 regions (Figure 3A). Like the *SNRPN-UBE3A* domain, it contains tandemly repeated C/D box snoRNA gene clusters that are imprinted, in this case *SNORD112/14q(0)* (*SNORD112*), *SNORD113/14q(I)* (*SNORD113*) and *SNORD114/14q(II)* (*SNORD114*), which are present in 1, 9 and 31 gene copies, respectively. These clusters, first identified in mouse as the non-coding RNA gene named *RNA imprinted and accumulated in nucleus (Rian)*, exhibit brain-dominant and brain-specific maternal expression in human and mouse, respectively [6, 87]. Most of these snoRNAs are intron-encoded and processed from a complex transcription unit mapping to *maternally expressed gene 8 (MEG8)* [6]. The imprinted domain *DLK1-DIO3* consists of the paternally expressed protein-coding genes *delta-like 1 (DLK1)*, *retrotransposon-like 1 (RTL1)* and *deiodinase, iodothyronine type III (DIO3)*, as well as the maternally expressed non-coding genes *MEG3*, *MEG8*, *antisense RTL1 (RTL1as)* and one of the largest microRNA (miRNA) clusters in the genome [88, 89]. These maternal genes and their maternally expressed intergenic transcripts are all expressed in the same orientation [6, 90-93], suggesting that they may form a large polycistronic transcription unit like *UBE3A-ATS* [93].

Mouse strains with uniparental duplications of chromosome 12 were used for the identification and characterization of DMRs in this domain [94]. The paternal intergenic DMR (IG-DMR), which is located upstream of *Gtl2/Meg3 (Gtl2)*, the mouse homolog of *MEG3*, has a methylation mark that is transmitted from the sperm as a gDMR [94]. The IG-DMR regulates the methylation status of the *Gtl2* DMR, which is a sDMR spanning the *Gtl2* promoter and its first exon and intron, and regulates monoallelic expression of all genes in this domain [95-97]. In contrast to the regulation of PWS-SRO by AS-SRO in the *SNRPN-UBE3A* domain [54], absence of the maternal IG-DMR results in *Gtl2* DMR hypermethylation and expression of the paternal chromosome, suggesting that the unmethylated maternal IG-DMR functions as an epigenotype switch that changes the default paternal status to the maternal status (Figure 3B, C) [95].

Gtl2, a non-coding poly-adenylated transcript, has multiple alternatively spliced forms of unknown function [98-100]. Short transcript variants (*Gtl2v3* and *4*) have 10 small exons, and long transcript variants (*Gtl2v1* and *2*) contain the largest (10 kb) exon at their 3' ends. An *in situ* hybridization analysis revealed that *Gtl2v1* is expressed in early neurons at 15.5 dpc but not in their progenitors at 12.5 dpc [101]. Because *Gtl2* regulates the occupancy of polycomb repressive complex-2 on chromatin through a direct interaction [102], *Gtl2v1* may be involved in neuron-specific gene expression.

A DNA FISH probe for the mouse *Gtl2* domain that encompasses *Rian* and *microRNA-containing gene (Mirg)*—regions equivalent to human *MEG8* and the large miRNA cluster—exhibited signals with one small compact signal (probably the inactive paternal allele) and one decondensed signal (probably the active maternal allele) in neurons but not glia, similar to *SNORD115* and *SNORD116* in the *SNRPN-UBE3A* domain (Figure 3A) [77]. DNA FISH probes flanking *Gtl2* revealed no chromatin decondensation. Combined RNA/DNA FISH analysis revealed that a spliced, nuclear-retained host gene of *RBII-36*, the snoRNA gene in rat *Dlk1-Dio3* domain, also accumulates near its transcription sites in brain [79].

Overview of the *GRB10* Domain

Growth factor receptor-bound protein 10/MEG1 (*GRB10*) is located on human 7p11.2–p12 and in mouse proximal chromosome 11 regions [103–105] and encodes an adapter protein [106]. *GRB10* is a unique imprinted gene that undergoes a brain-specific imprinting switch during development in human and mouse (Figure 4A, B, C). Human *GRB10* exhibits biallelic expression in almost all tissues and organs, except for the fetal brain, where it is expressed paternally [107–109].

In mouse, although the timing of the imprinting switch differs among strains, *Grb10* has been reported to be expressed maternally and paternally in brains of 11.5 and 14.5 dpc embryos with C57BL/6:CBA mixed genetic background, respectively [110], although it is only expressed maternally in most other fetal and adult tissues [109–111]. As with the U exons in the *Snrpn-Ube3a* domain, a series of downstream alternative promoters, 1C, 1B1 and 1B2, control this brain-specific paternal expression [109, 111–113].

In the region surrounding these brain-specific promoters, there is a gDMR named *Grb10*-DMR, which contains a methylated maternal allele and an unmethylated paternal allele [109, 111, 112]. A mouse-specific repeat sequence found in *Grb10*-DMR functions as a binding site for CCCTC-binding factor (CTCF) in a DNA methylation-sensitive manner [114]. The deletion of *Grb10*-DMR in the paternal allele changes the paternal transcripts in brain from a brain-specific isoform to a major isoform (Figure 4D) and unsilences paternal expression from the major promoter 1A in non-brain tissues, resulting in biallelic expression (Figure 4E). Maternal deletion of the *Grb10*-DMR produced no observable adverse phenotype in any tissue (Figure 4F, G). These results suggest that the paternal *Grb10*-DMR acts as an IC and represses the paternal major promoter 1A. Knockdown of CTCF in mouse embryonic stem cells (mESCs) by using short hairpin RNA also resulted in up-regulation of the major isoform with no change in the repressed brain-specific isoform. Although it is difficult to exclude indirect effects of CTCF knockdown, this result suggests that CTCF represses the paternal major promoter, possibly through its binding to *Grb10*-DMR [115].

Whereas DNA methylation and CTCF account for part of the repression mechanism, histone modification accounts for the activation mechanism (Figure 4A, B, C). The unmethylated paternal *Grb10*-DMR is activated in brain and repressed in non-brain tissues. It is enriched with active histone marks (H3K4me2 and H3K9ac) in brain; however, it has both active (H3K4me2) and repressive (H3K27me3) marks in embryo and kidney [113]. Repressed DNA-methylated maternal *Grb10*-DMR is enriched with repressive histone marks (H3K9me3 and H4K20me3) in both brain and non-brain tissues.

Experiments on *in vitro* neural differentiation of mESCs also revealed that the histone mark on the paternal *Grb10*-DMR changed from H3K27me3/H3K4me2 to H3K9ac/H3K4me2 during differentiation. Additionally, in mESC deficient for EED—a component of the polycomb repressive complex 2 that mediates H3K27 tri-methylation—the brain-specific promoter was derepressed, possibly on the paternal allele normally enriched with H3K27me3. These results suggest that the paternal brain-specific promoter near the *Grb10*-DMR is poised but silenced through the bivalent chromatin domain (H3K4me2/H3K27me3) in undifferentiated cells and most non-brain tissues, whereas replacement of repressive H3K27me3 with active H3K9ac during neural differentiation activates the paternal brain-specific promoter.

Figure 3. Overview of the *Dlk1-Dio3* domain. (A) Schematic representation of the *Dlk1-Dio3* domain, derived from the mouse and rat experiments. The alleles exhibiting maternal and paternal imprinted expression patterns are depicted in dark gray and light gray, respectively, whereas silenced alleles are depicted in black. Maternally expressed non-coding RNAs (*Gtl2*, *Rtl1as*, *snoRNA-HG* transcripts and *Mirg*) constitute part of a large polycistronic transcription unit. The cluster of tandemly repeated *snoRNA* genes contains intron-encoded *snoRNAs* (triangles) and nuclear-retained *snoRNA-HG* transcripts (framed rectangles), which accumulate near their transcription sites. The *miRNA* and other genes are symbolized as vertical bars and rectangles, respectively. The orientation of transcription is shown by arrows. Methylated and unmethylated DMRs are indicated as lollipops with black and white circles, respectively. The black bar below the map indicates the location of the DNA FISH probe utilized to show the neuron-specific chromatin decondensation (probably the active maternal allele). (B) Maternal transmission of the *IG-DMR* deletion (white triangle) in mouse results in bidirectional loss of imprinting of all genes in the domain. (C) Paternal transmission of the *IG-DMR* deletion in mouse does not affect imprinting.

Figure 4. Overview of the *Grb10* locus. (A) Schematic representation of the region spanning mouse *Grb10* exons 1A-17. Exons are designated as vertical bars. The promoter region focused in following panels (B-G) is marked by a rectangle. (B, C) Allele-specific expression patterns and epigenetic features in (B) brain and (C) non-brain tissues and undifferentiated cells. *Grb10*-DMR and CTCF are depicted as ovals labeled IC (imprinting center) and CTCF, respectively. CTCF represses the paternal major promoter, possibly through its binding to the unmethylated paternal *Grb10*-DMR. Replacement of repressive H3K27me3 with active H3K9ac activates the paternal brain-specific promoter near the *Grb10*-DMR. In contrast, replacement of active panacetylated H3 and H4 with repressive H3K27me3 represses the maternal major promoter in neuron. (D, E) Paternal transmission of the *Grb10*-DMR deletion (white triangles) results in derepression of the major promoter in (D) brain and (E) non-brain tissues and undifferentiated cells. (F, G) Maternal transmission of the *Grb10*-DMR deletion does not affect imprinting in (F) brain or (G) non-brain tissues and undifferentiated cells.

Experiments on primary cultured cells revealed similar allele-specific histone modifications in the major promoter. The maternal major promoter is activated in non-brain tissues and repressed in brain. It is enriched with activating chromatin marks (panacetylated H3 and H4) in fibroblasts, but with repressive H3K27me3 in primary neuronal culture [112]. The repressed paternal major promoter is enriched with repressive H3K27me3 in both fibroblasts and primary neuronal cultures.

CONCLUSION

The *Dlk1-Dio3* and *Snrpn-Ube3a* domains are similar, for example, in that they are involved in transcription of the snoRNA clusters or their upstream brain-specific non-coding transcripts (*Gtl2v1* in the *Dlk1-Dio3* domain and U exon transcripts in the *Snrpn-Ube3a* domain) and that accumulation of spliced nuclear-retained host genes occurs at their transcription sites. Although *Gtl2v1* is an alternatively spliced isoform whose promoter is used for transcription in several tissues, these shared features may play a role in establishing the differential chromatin organization of the two parental alleles and brain-specific expression of the downstream imprinted genes (maternal *Mirg* in the *Dlk1-Dio3* domain and paternal *Ube3a-ATS* in the *Snrpn-Ube3a* domain). The treatment with ASOs that target *Snord116* degraded almost all of the *Snord116* and *Snord115* transcripts but approximately half of the *Ube3a-ATS* precursor transcripts [86], supporting the existence of several types of *Ube3a-ATS* transcripts. The *Snord116* transcripts are embedded in the *Ube3a-ATS* transcripts driven from U exons or exon 1, but not in the shortened type of *Ube3a-ATS* transcripts driven from the TSSs near *Snord115*. The similarities between *Dlk1-Dio3* and *Snrpn-Ube3a* domains (existence of several types of transcripts, neuron-specific chromatin decondensation, and localization of transcripts at their transcription sites) may provide a clue to the complicated gene regulation in these domains (Figure 1A, 3A). The similarity between *Grb10* transcription and U-exon transcription is the existence of brain-specific promoters (Figure 1A, 1B, 2, 4B, 4C). Although the epigenetic features of the brain-specific promoters in U exons are not yet clear, the regulation of the promoter switch in *Grb10* may provide some insight.

The role of brain-specific U exon transcripts in the brain-specific expression of *Ube3a-ATS* also remains to be clarified. The regulation of paternal *Ube3a* silencing through *Ube3a-ATS* also requires further study. Further functional experiments to investigate the regulatory regions or functional elements of U exon transcripts, snoRNA clusters and *Ube3a-ATS* will be essential to elucidate the mechanisms that regulate brain-specific imprinting. We consider that longitudinal analyses by *in vitro* neural differentiation [16, 47, 75, 113, 116] will be a useful tool to clarify the developmental changes of the imprinting marks and gene regulation of the brain-specific imprinted genes.

PHARMACOGENOMICS FOCUSING ON PHASE TWO METABOLIZING ENZYMES

Kung-Hao Liang*

Chang Gung Memorial Hospital, Taoyuan City, Taiwan

ABSTRACT

Treatment of human diseases in general has dual goals: to treat effectively, at the cost of minimal adverse side effects. However, person-to-person differences on drug efficacy and adverse reactions have been frequently observed. Pharmacogenomic studies intend to address such differences based on personal genomic variants such as single nucleotide polymorphisms. In the past, success has been achieved on the identification of major histocompatibility complex genomic variants which are associated to immune-mediated adverse drug effects. Additionally, genomic variants on the direct drug targets have been found to be associated to drug efficacy. Besides immunological and drug-target factors, one other critical factor is on the drug metabolism mediated by various xenobiotic metabolizing and detoxification enzymes. They determine how quickly the drugs can be metabolized and then excreted from the body, thereby affecting drug efficacy and toxicity.

Human xenobiotic metabolizing enzymes are categorized by their phases in the metabolizing processes: the modification phase (phase 1), the conjugation phase (phase 2), and further modification and excretion (phase 3). Previously, genes involved in phase 1 have been extensively studied in pharmacogenomics. In comparison, genes in phase 2 received less attention, despite the fact that they are no less important. These genes include Uridine Diphospho-Glucuronosyltransferases and others. This Chapter presents the genomic variants on phase 2 genes which can account for the drug efficacy and adverse reactions.

INTRODUCTION

The human genome encodes the blueprint of the human body. It is the shared human heritage yet every person has a slightly different version of the genome. The variations between versions often occur in hotspots, such as the single nucleotide polymorphisms or short tandem repeats, which could cause personal difference in health and disease. All of us suffer from diseases sometime in our life, either mild or severe. Contemporary treatments of diseases often follow medical guidelines; and the drugs are prescribed by their optimum doses established by an extensive series of preclinical lab tests, large-scale clinical trials and post-market studies. Under such standalized treatments, different levels of responses and toxicity are often observed in different people. Importantly, life-threatening adverse reactions may occur to certain patients for unknown reasons. Patients' age, gender and ethnicity cannot explain the observed variations completely. The remaining unexplained variations could be ascribed to the personal genetic background.

Pharmacogenomics studies aim to elucidate the unexplained variations by interrogating the genotype-efficacy/safety relationships. The candidate gene approach interrogates a focused panel of genes which are hypothesized to underlie the investigated variation. Alternatively, the genome-wide approach interrogates the entire genome, using multiplexing platforms such as SNP microarrays or high-throughput sequencing techniques. Expected results are genes where different genotypes associated to different outcomes of the same treatment (efficacious vs. non-efficacious, or with adverse effects vs. non-adverse effects).

Till 2014, ascertained genes often belong to one of three typical categories. The first class is involved in the targeting mechanisms of drugs. For example, personal variations of the promoter sequence of the IL28B gene, also known as Interferon lambda, was found to account for the difference on the efficacy of interferon-based treatments of chronic hepatitis C infection (Ge et al., 2009). IL28B was considered the downstream genes in the interferon pathways.

The second class is the immunological genes. Variants on major histocompatibility complex genes can be used to identify high-risk subjects of life-threatening allergic reactions such as the Steven-Johnson's syndrome, if they were given Carbamazepine which is an anticonvulsant and a mood-stabilizing drug (Chen et al., 2011). A prospective study with 4877 subjects in Taiwan showed that conducting the genetic test before the use of Carbamazepine can achieve zero incidence of Steven-Johnson's syndrome, as opposed to a historical incidence of 0.23% (Chen et al., 2011).

The third class genes encode xenobiotic metabolizing enzymes. Some drugs can be excreted in its original form without being chemically modified by the body. Others undergo a series of modifications mediated by enzymes in the liver, kidney and gastrointestinal tract. Such modification include three phases, the modification phase (phase 1), the conjugation phase (phase 2), and further modification and excretion (phase 3) (Omiecinski et al., 2011). Not surprisingly, genomic variations affect the enzymatic activities, thereby affecting the effective dose concentrations of the drugs. Phase I enzymes often involve the oxydation, reduction and hydrolysis of the substances to produce polar, hydrophilic metabolites. Typical phase 1 enzymes, such as CYP2C9 or CYP4A6 in the cytochrome P450 gene family, are the metabolizers of warfarin. The genetic variants can be utilized to adjust the administration dosage of warferin (The international Warfarin pharmacogenetics consortium, 2009).

Phase 2 enzymes can increase the polarity and water solubility of substrates for their ease of excretion by bile or urine (Omiecinski et al., 2011). Substrates are modified by the covalent attachment of small, endogeneous, hydrophilic molecules including glucuronic acid, sulfate, or glycine. Different modifications are catalyzed by different groups of enzymes.

UGT GENE SUPER FAMILY ENCODES CRITICAL PHASE TWO METABOLIZING ENZYMES

The Uridine-Diphospho Glucuronosyltransferases (UGT) gene super family encodes enzymes whose major roles are to catalyze glucuronidations of substrates, be them xenobiotic drugs, endogeneous hormones or bilirubin. The molecular weights of these enzymes are around 60 kilodaltons. An UGT protein has a transmembrane domain near the C-terminus, a substrate-binding domain near the N-terminus, and an UDPGA domain in the middle for catalyzing glucuronide conjugations. The transmembrane domain anchors the protein into the golgi apparatus of the cells. The human UGT super family comprises two families, UGT1 and UGT2. The UGT1 family has 9 genes, all of them located in the forward strand of chromosome 2q37.1. They have distinct first exons but share exons 2-5. Table 1 summarizes the currently known UGT1 variants. Some variants can encode changes of amino acids in exon 1 which may confer variations on substrate specificity and binding efficacy. Other variants may play regulatory roles by affecting the transcription and translation of genes. Note that variants near the shared exons 2-5 may affect all UGT1 genes.

Table 1. Genomic variants of the UGT 1 genes sorted by their locations in human chromosome 2. Variants may encode amino acid changes which therefore affect the enzymatic functions or alternatively, they may encode the difference of regulatory effects

The UGT2 family can be further subdivided to UGT2A and UGT2B subfamilies based on the disparity of amino acid sequences. The UGT2B genes include 7 members, where UGT2B10, 2B7 and 2B28 reside in the forward strand, while UGT2B17, 2B15, 2B11 and 2B4 reside in the reverse strand of the chromosome 4q13.2 regions. Table 2 summarizes the currently known UGT2 variants.

Table 2. Genomic variants of the UGT2 genes sorted by their locations in human chromosome 4. Variants may encode amino acid changes which therefore affect the enzymatic functions or alternatively, they may encode the difference of regulatory effects. Genes are encoded either in the forward or the reverse strand of the chromosome

* Numbers represent the amino acid locations of the variants. Since variants are sorted in the ascending order by the chromosomal orientation, the amino acid locations appear in a descending order in those genes reside in the reverse strand.

Drugs metabolized by UGT enzymes are only partially known (Guillemette et al., 2014; Stingl et al., 2014). Commonly prescribed drugs and endogenous molecules confirmed to be metabolized by UGT enzymes are summarized in Figure 1 for a snapshot of the current

knowledge. Genes are organized by a hierarchical clustering method based on the pairwise correlation of their substrate profiles. UGT2B28, 2B11 and 1A5 have no clearly confirmed substrates currently. UGT1A4, 2B15, 2B7, 1A9 and 1A1 has been discovered to be able to metabolize multiple drugs. UGT1A7 and 1A10 have high correlation in their substrate profiles. In fact, they can only metabolize SN-38 but not the other molecules in the current list. UGT1A1 and 1A3, as well as UGT1A6 and 2B4 are also pairs of enzymes with similar substrate profiles (Figure 1).

SN-38 is the active-form metabolite of Irinotecan, which is an approved chemotherapeutic agent for treating colon cancers. SN-38 can be further metabolized by multiple enzymes including UGT1A1, 1A7, 1A9 and 1A10 to become capable of being excreted from the human body (Figure 1). Since SN-38 has a narrow therapeutic index, poor phase 2 metabolisms by the UGT genes may result in the accumulation of SN-38, causing adverse effects including diarrhea and neutropenia (Iyer et al., 2002). Thus, personal variants of the four UGT genes may account for the adverse effects. The most commonly studied variant is rs8175347, a short tandem repeat with 5-8 repetitive "TA" nucleotides in the UGT1A1 promoter region. The higher number of "TA" has been shown to be associated to poor phase 2 metabolism of SN-38 by UGT1A1 (Iyer et al., 2002).

Sorafenib is a multikinase inhibitor approved for the treatment of advanced hepatocellular carcinoma and renal cell carcinoma. It was reported to be a potent inhibitor of UGT1A1, while at the same time metabolized by UGT1A9. We can therefore infer that combined usage of sorafenib and irinotecan may cause adverse effects due to the suppression of UGT1A1 by sorafenib, which suppressed the metabolism of SN-38.

Other examples of one-to-many drug-UGT relationships include mycophenolic acids, which are immunosuppressants metabolized by UGT1A8, 1A9 and 2B7 (Picard et al., 2005), as well as olanzapine, which is an antipsychotic metabolized by UGT1A4 and 2B10 (Figure 1). Tamoxifen, an antagonist of estrogen receptors for treating estrogen-positive breast cancers, is metabolized by UGT1A4 and 2B15 (Figure 1). Resistance to the treatment, as well as adverse effects on deep-vein thrombosis and hot flashes, has been observed in some patients.

Figure 1. UGT enzymes arranged by the correlations of their substrate profiles. The right panel shows the pairwise correlations of substrate profiles by grey-scale levels. The left panel is an enzyme-substrate relationship matrix where a dark cell represent a well-established relationship summarized in a review paper (Guillemette et al., 2014). UGT enzymes with higher correlations of the substrate profiles are presented in nearby rows by a hierarchical clustering method of the Generalized Association Plot software (Chen, 2002).

FUTURE PERSPECTIVE

The above analysis shows that genomic variations on the UGT genes can certainly affect drug metabolism, causing differences on drug efficacy and safety. However, the relationship may be complex, as a drug can be metabolized by multiple UGT genes (Figure 1). Furthermore, these genes have many common variations, each of which may exert certain degree of effect on the drugs. Fortunately, multiplexing technique is already commercially available for assessing a collection of variants in a single assay. Genotypes of most of the variants in Tables 1 and 2 can be easily detected by the Affymetrix DMETTM Plus microarrays. With such information available, treatment can be tailored personally for maximal efficacy and minimal toxicity.

New drugs are constantly being developed to fulfill two major goals: to treat effectively and to elicit minimal adverse effects, both has been primary concerns of healthcare authorities. Regarding safety, how efficient the drugs can be metabolized, and whether the medication will elicit unwanted or unexpected adverse effects are two major issues. Although pharmacokinetic studies are routinely performed in pre-clinical studies to identify their metabolizing enzymes, the genotypes are rarely used currently for the design of clinical trials in selecting adequate patient groups. This may be one major reason for the high attrition rate of drug developments at this moment. We will witness soon that the genomic variants being effectively incorporated for the successful development of drugs.

SEXUAL DIMORPHISM IN INSECT LONGEVITY: INSIGHTS FROM EXPERIMENTAL EVOLUTION

Jelica Lazarević^{1,*}, Biljana Stojković² and Nikola Tucić¹

¹Institute for Biological Research, University of Belgrade, Belgrade, Serbia

²Faculty of Biology, University of Belgrade, Belgrade, Serbia

ABSTRACT

In species with separate sexes, gender differences in longevity are widespread and the extent and direction of these differences varies tremendously among taxa. To understand sexual dimorphism in longevity and explain how different forms of selection shape longevity and other fitness-related traits within and among species, it is important to obtain information on the genetic architecture (the number of genes and degree of inter- and intra-genic interactions) and various mechanistic causes which underlie mortality variation between the sexes. Here we review recent empirical studies on gender differences in longevity in insect species, from both mechanistic and evolutionary perspective. Whenever it was possible, we focus on data obtained from the laboratory evolution experiments because the study of evolution under controlled conditions may provide valuable evidence not only for the effects of natural and sexual selection in shaping sex-specific longevities and mortality rates but also it offers novel insights into the mechanistic basis of these differences.

INTRODUCTION

Over the last 30 years our understanding of the proximate (mechanistic) causes involved in age-specific decline in survival and reproductive performance (senescence or ageing) has been improved dramatically. However, many fundamental questions concerning the relative importance of evolutionary mechanisms (i.e., ultimate causes: Mayr 1961) that directly or indirectly influence the rate of senescence are not entirely answered. For example, despite the

* Corresponding Author's Email: jellaz@ibiss.bg.ac.rs (Institute for Biological Research, University of Belgrade, Despot Stefan Blvd. 142, 11000 Belgrade, Serbia).

fact that we now have a plethora of information with respect to longevity differences in genetic architecture and physiology between females and males (see below), ultimate causes why females and males age at different rates are still poorly understood.

Gender differences in longevity are widespread in insect species although the extent and direction of the difference depend on species phylogenetic position, environmental conditions and mating status (Table 1). Moreover, even when females and males have the same longevity, they may differ in demographic parameters, i.e., the shape of age-specific survival curves.

Antagonistic relationship between somatic maintenance and reproduction has been revealed by many longevity-extending genetic and environmental manipulations, as well as in artificial selection and laboratory evolution experiments (Hughes and Raynolds 2005). The cost of reproduction in many insects is frequently manifested as increased mortality rate of mated relative to unmated females. Mating is energetically costly to females not only because of high amount of resources allocated to egg production but also due to impairment of immune functions (Rolff and Siva-Jothy 2002; Fedorka and Zuk 2007), oxidative damage (Archer et al. 2012a) and direct physical harassment by males (Morrow and Arnquist 2003). In general, mated individuals live shorter than virgins, although many exceptions from this ‘rule’ (Lazarević 1994; Carey et al. 2002; De Loof 2011) imply that mating costs and benefits for female longevity may vary among different populations (Shuker et al. 2006) and species (Rönn et al. 2006). For example, multiple mating is beneficial for *Callosobruchus maculatus* (Rönn et al. 2006) and *Gryllus lineaticeps* (Wagner et al. 2001), detrimental for *C. chinensis* (Rönn et al. 2006), *Drosophila buzzati* (Scannapieco et al. 2007, 2009), *Acanthoscelides obtectus* (Šešlija et al. 2008), *Gryllus bimaculatus* (Bateman et al. 2006), and does not affect female longevity in *Telostylinus angusticollis* (Adler et al. 2013) and *Gryllodes sigillatus* (Ivy and Sakaluk 2005).

Importance of genetic background in shaping insect mortality rates and sexual dimorphism in longevity was confirmed in many studies in which life-span of unmated (virgin) individuals were compared among different natural populations or laboratory lines (Yilmaz et al. 2008; Iliadi et al. 2009) and species of *Drosophila* (Promislow and Haselkorn 2002). *D. hydei* females live about 20% shorter than males, while life-span of *D. virilis* females is almost twice as long as male's (Promislow and Haselkorn 2002). *Canton S* and *Oregon R* lines of *D. melanogaster* differed in mean longevity of females, but not males, when they were kept individually, while in a single sex group of 20 individuals *Oregon R* females live longer and males live shorter comparing to *Canton S* line (Iliadi et al. 2009). Same authors showed that sexual dimorphism for longevity of virgin individuals was expressed only in *Oregon R* line, where females outlived males due to lower initial mortality rate. However, the results with *Oregon R* and *Canton S* lines may vary depending on experimental design (Cui et al. 2001; Moskalev et al. 2009; Vaiserman et al. 2013). As expected, QTL and quantitative genetic analysis revealed that genes affecting longevity are sex-specific and environment specific (Nuzhdin et al. 1997; Šešlija and Tucić 2008; Hallsson and Björklund 2011) implying that evolution of longevity may proceed by different mechanisms in females and males (Tower and Arbeitmann 2009) and may take different courses in diverse environmental circumstances.

Generally, life-span duration is influenced by female fitness-related traits more strongly compared with males, which is an expected consequence of positive correlation between female longevity and realized fecundity. Interestingly, this association between fecundity and life-span is even more important under stressful conditions. There is a plethora of evidence that females and males differently respond to the variations in environments. Substantial sex-specific plasticity (i.e., significant „sex $\times$ environment“ interaction) in adult longevity has been detected in environments with varying nutritional value of diet (Adler et al. 2013; Zajitschek et al. 2009b), temperature (Norry and Loeschcke 2002), oxidative stress (Lazarević et al. 2013), etc. (reviewed in Section 3.3. of this chapter). As will be elaborated in proceeding sections of this chapter, different evolutionary mechanisms can be involved in shaping sexual dimorphism in longevity and patterns of ageing, as well as in disparity of environmental sensitivity of these characteristics among genders.

First, natural selection acting either directly on life-span duration in the two sexes or indirectly through environmental effects on other fitness-related traits (e.g., developmental time, body size, fecundity, etc.) can mould longevity patterns in specific habitats (Section 1). For example, in a lepidopterous species *Pararge aegeria*, temperate (Atlantic island of Madeira) and north populations (southern Sweden) exhibit phenological differences in adult eclosion. Since eclosion is more synchronized in north than temperate populations, northern females are available to males during a shorter period of time which weakens selective pressure for long life in males and promote higher sexual dimorphism in longevity (Gotthard et al. 2000).

Another evolutionary force which shape insect longevity and mortality rate is sexual selection (Section 2). Sexual selection occurs whenever sexes differ in investment to reproduction. Theory predicts that males adopt “live fast – die young” strategy while females follow “low-risk, low-wear-and-tear” strategy. Male-biased mortality is usually related to risky behaviour, such as male sexual competition in polygamous mating systems, and higher allocation of resources to reproduction and secondary sexual traits which improve sexual presentation. In monogamous species, or species where mating success increases with age, selection may favour lower mortality in males than females (Bonduriansky et al. 2008).

Effects of mating on longevity depend on mating system of a species. Comparisons of virgin and mated individuals between polyandrous and monoandrous species of fireflies from Lampyridae family revealed that in polyandry longevity was not affected by copulation while in monoandry single mated females doubled their lifespan relative to virgin counterparts (Fu et al. 2012). Analyses of fireflies from genus *Photinus* showed that, in comparison with males from monoandrous species, polyandrous males allocate more resources towards reproductive tissues, which maximize their ability to produce nuptial gifts and increase reproductive success under high levels of male-male competition (Demary and Lewis 2007). Among lepidopterous species, investment in early reproduction in females is negatively correlated with longevity and degree of polyandry possibly because polyandrous females obtain more nutrients through nuptial gifts than monoandrous ones (Jervis et al. 2005). Intra-species comparisons in *Acanthoscelides obtectus* pointed that monoandrous conditions, inadvertently created during laboratory evolution for early reproduction and short-life, decrease the magnitude of sexual dimorphism in longevity (Stojković and Savković 2011).

As stressed by Bonduriansky et al. (2008), females and males do not differ in the level but rather in the nature and scheduling of reproductive effort. In natural conditions, *Teleogryllus commodus* females live longer, show lower baseline mortality and higher mortality rate than males. At the same time, long life is related to early reproductive effort in females and late reproductive effort in males (Zajitschek et al. 2009a). Under laboratory conditions, similar age-dependent pattern of reproduction has been recorded, but males outlived females due to lack of extrinsic mortality causes (Maklakov et al. 2009b). This implies that environmental conditions determine optimal relationship between longevity and reproduction.

1. THE ROLE OF NATURAL SELECTION IN SHAPING INSECT LONGEVITY

Fundamental to the standard theory of ageing is the idea that senescence is a result of decreasing intensity of natural selection after the onset of reproduction (Medawar, 1952; Williams 1957; Hamilton 1966). This means that any delay in the start of reproduction should lead to a postponement of senescence. This prediction has received quite extensive support, primarily in the experimental evolution studies that have been conducted on three insect species, *Drosophila melanogaster* (e.g., Rose and Charelsworth 1980; Rose 1984; Partridge and Flower 1992), *Acanthoscelides obtectus* (Tucić et al. 1996, 2004) and *Musca domestica* (Reed and Bryant 2000). By manipulating the ages at which selection is strong (i.e., using early vs. late reproduction selection regimes), these studies have shown that natural selection is indeed able to shape the evolution of ageing patterns. Experimental evolution studies have also suggested that an important genetic mechanism underlying postponed senescence could be antagonistic pleiotropy, which assumes the existence of alleles that improve early-life performance but have deleterious effects at later ages. Because the intensity of natural selection declines with advancing age, these alleles will increase in frequency and cause the senescence due to their negative effects on late-age performance (Williams 1957). The observations of a trade-off between early and late life performance, as in the above mentioned studies, are empirical support of the antagonistic pleiotropy hypothesis. A second prediction of this hypothesis is the existence of negative genetic correlation between early and late-life fitness-

related traits in populations with frequent segregating variation. These expectations also received experimental confirmation (e.g., Tucić et al. 1988), although in a less consistent way (Rose et al. 2005). It is noteworthy that an “early-late” trade-off in performance is also integral part of the “disposable soma” hypothesis (Kirkwood 1977), which proposes that senescence is caused by accumulation of damage due to processes that result in progressive decrease of the amount of resources allocated toward somatic maintenance and repair. This hypothesis assumes a physiological trade-off between reproduction and somatic maintenance and predicts that investment in reproduction (or somatic maintenance at earlier ages) should result in decrease of performance at later ages.

However, senescence might arise because of the accumulation of mutation with deleterious effects confined to later ages (Medawar 1952). Mutation accumulation hypothesis assumes that, because the strength of natural selection declines with age, genetic drift and recurrent deleterious mutations produce decline in individual performance at advancing ages. One of the effects of these processes could be upsurge of inbreeding depression for fitness-related traits with age. This is empirically testable prediction because crosses between populations, if they are subjected to age-specific mutation accumulation, should produce higher hybrid vigour (as the consequences of increased inbreeding load within populations) on fitness-related traits at later ages relative to the early ages (Charlesworth and Hughes 1996). Several studies of *Drosophila* have documented age-specific hybrid vigour for longevity and other fitness-related traits (Charlesworth and Hughes 1996; Hughes et al. 2002; Gong et al. 2006), but few others have shown that this relationship between age and inbreeding load varies among populations or are sex-specific (Lesser et al. 2006; Reynolds et al. 2007; Vaiserman et al. 2013). Furthermore, studies on two seed beetle species (*Callosobruchus chinensis*; Tanaka, 1990; and *C. maculatus*, Fox et al. 2006; Fox and Stillwell 2009) have produced results that were inconsistent with mutation accumulation hypothesis.

Experimental evolution studies, where replicate populations are exposed to different age-specific selection regimes, are especially suitable tool for testing mutation accumulation hypothesis. Here, the critical test of the hypothesis is the exploration of hybrid vigour in late-life fitness component in crosses between replicate populations subject to early reproduction. In study on short-lived early-reproducing *D. melanogaster* experimental populations, Rose et al. (2002) did not find differences between hybrid and nonhybrid populations in late-mortality rates implying that mutation accumulation could not be considered as a relevant explanation of genetic mechanisms involved in late mortality. Also, in subsequent work of Borash et al. (2007) on the same set of fruit flies populations no detectable heterotic effect was seen for female and male longevity and their hybrids. The only fitness-related trait whose age-specific changes were consistent with mutation accumulation hypothesis was male mating ability. Interestingly, in the same kind of experiment on the seed beetle *Acanthoscelides obtectus*, in contrast to females, mating ability of males exhibited inbreeding depression (Đorđević et al., in preparation), indicating that underlying genetic mechanisms for reproductive effort differed between sexes in populations selected for early reproduction and short life. It is noteworthy that, in these nonhybrid populations of the seed beetle, virgin males outlived virgin females, while in the long-lived nonhybrid populations females lived longer than males (sex-reversal with respect to longevity in the short-lived populations was also observed in Stojković and Savković 2011). It seems that in short lived populations evolutionary course reversed sex-specific mortality rates being that in the ancestral experimental population (i.e., base population), from which short- and long-lived populations have been derived, the longevity of

females were substantially higher than in males (Šešlija et al. 2008). Although this finding of sex-specific responses to inbreeding is quite unexpected, it is consistent with the result obtained by Bilde et al. (2009) in another seed beetle, *Callosobruchus maculatus*.

As pointed out by Bilde et al. (2009), one possible explanation as to why inbreeding, which increases homozygosity, affects males less than females presumes that the heterogametic sex (males in *A. obtectus* and *C. maculatus*) does not suffer from increased expression of X-linked recessive deleterious mutations. Another potential explanation for the sex-specific sensitivity to inbreeding is that males evolve mechanisms to counteract the negative effect of mitochondrial mutations on longevity, possibly by nuclear genes that influence expression of the mitochondrial genes (Yee et al. 2013). This hypothesis is based on the fact that mitochondrial genomes commonly function sub-optimally when expressed in males, as a consequences of maternal inheritance of mitochondrial genes and and their selection within females. Therefore, it is possible that the mismatch between mitochondrial and nuclear genes, which affect longevity, may be more pronounced in the inbred females than males. Consistent with this idea is the finding that in *D. simulans* females homozygous for some mutations in one nuclear-encoded mitochondrial protein pay a greater survival cost than do males (Melvin and Ballard 2011). The role of mitochondria in ageing process and sex-specific mortality patterns will be more elaborated in Section 3.3.1.

2. SEXUAL CONFLICT AND EVOLUTION OF SEXUAL DIMORPHISM IN LONGEVITY

The opposing sex-specific responses to inbreeding observed in the two seed beetle species indicate that an optimal longevity has evolved not only as a results of trade-offs between reproductive performance early and late in life, but also that this process could be influenced by changes in patterns of sexual selection. Bilde et al. (2009) and Maklakov and Lummaa (2013) argue that it is likely that sex-specific selection, which assumes that the optimal reproductive strategies of females and males differ, has also played an important role in the evolution of sexual dimorphism in longevity and mortality rates. Sexually divergent selection may produce two distinct forms of conflict with very different evolutionary outcomes. Intra-locus sexual conflict, which occurs whenever reproductive behaviours that are optimal for one sex are deleterious for the other sex, prevents traits which are shared by the sexes to evolve to their sex-specific phenotypic optima, because the shared traits have a common genetic basis. In contrast, inter-locus conflict involves different genes in each sex and it can cause open-ended cycles of adaptation and counter-adaptation between the sexes (Parker 1979). Since intra-locus conflict could lead a subset of genes coding for the shared traits to sex limited expression (see e.g., Lande 1980; Bonduriansky 2007 and references therein), it is expected that traits under this form of sexual selection possess the sex-specific genetic architecture. This prediction is supported in both seed beetle species, *C. maculatus* (Fox et al. 2004) and *A. obtectus* (Šešlija and Tucić 2008). In both studies it has been shown that genes coding for extended longevity were dominant in females and recessive in males, which raises the possibility that inbreeding could decrease female longevity and, at the same time, increase life span in males. Thus, it seems that the genetic architecture of longevity in these species evolves in a way that reduces genetic constraints on the independent evolution of the sexes. In one experiment on *D.*

melanogaster, Wayne et al. (2007) found that variation in gene expression was mostly the result of non-additive interactions between genes in females, while in males additive interactions of alleles prevailed. Having in mind that additive genetic variation respond to selection more readily, it is possible that genes affecting longevity may be more exposed to selection in males than in females, thereby reducing inbreeding load for male-specific deleterious mutations in populations.

Comparison of laboratory strains of *D. melanogaster* revealed that large part of transcriptional variation can be attributed to sexual dimorphism especially for genes expressed in germ-line tissues (Jin et al. 2001; Wayne et al. 2007; Baker et al. 2007; Wilson et al. 2013). These studies, in which sex-specific differences in the mode of transcriptome inheritance were identified, provide an additional insight into the gender differences in genetic architecture of the fitness-related traits. Gene expression pattern changes in response to mating and sexual selection and depending on mating system can have different evolutionary outcomes in females and males (Mank et al. 2013). For example, in *Drosophila* males, higher changes in transcription level during ageing was revealed for genes affecting protein synthesis, whereas in females starch and sucrose metabolism was more affected (Wilson et al. 2013). Magwire et al. (2010) analyzed effects of longevity-extending mutations on transcriptional pattern and found that each mutation had at least one deleterious pleiotropic effect and that these effects differed between the sexes.

The key feature of intra-sexual conflict in the evolution of longevity and ageing is that selection is working in the opposite directions in females and males, i.e., when female fitness is associated with increased longevity, male longevities should co-evolve, because of the intersexual genetic correlation for longevity, resulting in decreased male fitness. The predicted sex-specific relationship between fitness and longevity has been obtained in the seed beetle *C. maculatus*, where divergent sex-specific selection on longevity has been conducted (Berg and Maklakov 2012). In this experimental evolution study, selection for long-life produced replicate populations with low male fitness and high female fitness. More results implying that different reproductive strategies may lead females and males towards different optima in longevity has also been shown in the decorated cricket, *Gyllodes sigillatus* (Archer et al., 2012b). The sexual dimorphism in this species arises because females and males alter their reproductive effort with age; the reproductive effort increases with age in males but not in females. These strategies have led to an interesting evolutionary outcome - males live longer and age more slowly than females. Consistent with the view that intra-locus sexual conflict has the potential to play an important role in the evolution of sex differences in longevity and ageing are also findings obtained by Lewis et al. (2011) on indian meal moth, *Plodia interpunctella*. By using quantitative genetic approach these authors have shown that the pattern of multivariate selection acting on longevity and two other sexually dimorphic fitness-related traits was working in the opposing directions in the two sexes.

Several recent studies have indicated that some sexual adaptations in males, such as genital armour or increased toxicity of seminal fluid that polygynous males evolved to maximize their sperm competitive ability (possibly by destroying or disabling the sperm of previous mates), should lead to evolution of accelerated senescence in females. For example, in the laboratory evolution experiment on *C. maculatus*, Maklakov et al. (2007) have shown decreased rates of mortality and elevated longevity in monogamous virgin females relative to virgin females evolved under enforced polyandry. Similarly, female *D. melanogaster* had longer life-span after mating with males from lines selected for monogamy relative to females mated with

polyandrous males (Holland and Rice 1999). Thus, removal of sperm competition may have promoted evolution of more benign mates for females, which liberated them from costly counter-adaptations. Also, under such conditions, males did not trade-off resources between traits associated with male-to-male competition and longevity. Monogamous and polyandrous mating regimes have also been applied in other insect species: *D. pseudoobscura* (Bacigalupe et al. 2007), the dung flies, *Sepsis synipsea* and *Scathophaga stercoraria* (Hosken et al. 2001; Martin and Hosken 2003), the dung beetle, *Onthophagus taurus* (Simmons and Garcia-Gonzalez 2008). These studies support the idea that sexual selection can lead to significant gender differences in longevity and mortality rates.

Despite the potential importance of combined effect of sexual selection and natural selection for the evolution of longevity and mortality rates, there are few empirical studies that have attempted to tease apart these two evolutionary mechanisms. Maklakov and Fricke (2009), Maklakov et al. (2009a) and Maklakov et al. (2010) pioneered the approach of exploring consequences of simultaneous manipulations of mating systems (monogamy vs. polyandry) and age-specific selection (early vs. late reproduction) on the evolution of longevity in *C. maculatus*. The results showed that natural selection affects the evolution of longevity much more than did sexual selection.

The general effects of the conflict between members of the same sex over opportunity to mate on the evolution of longevity and mortality rates can mediate, to some extent, the species-specific adaptations. For example, because mated females with repressed oviposition live longer than virgin females, it seems that seed beetle (*A. obtectus*) females under starvation benefit from nutrients and/or water received with ejaculates (Tucić et al. 1996; Maklakov et al. 2005; Šešljija et al. 2008). Since *A. obtectus* is capital breeder (adults do not need water or food to reproduce successfully), this can be treated as an important female adaptation. Similar effects of male ejaculates on female fitness have also been observed in other bruchid insects (Savalli and Fox 1999; Edvardsson 2007).

To date, the role of sexual conflict in shaping longevity has been tested in very few species and focusing mostly on the consequences of conflict from the female's perspective. From the male's point of view, Hall et al. (2009) have revealed that nuptial feeding could be an important mechanism of antagonistic interactions between females and males and that in some cases, when resources are scarce, male reproductive investment in offspring, together with the associated costs of mating, can exceed the costs experienced by females. Under these circumstances, as pointed out by Hall et al. (2009), "the sex roles can reverse with females actually competing for access to males as potential food sources" (p. 873). In other words, changes in nature of sexual conflict may shape longevity and mortality rates of males in the same way as elevated sexual conflict do in females.

3. MECHANISTIC CAUSES OF SEX-SPECIFIC AGEING

Many experiments have shown that various genetic and environmental interventions exhibit sex-specific effects on longevity. Because of these gender differences Burger and Promislow (2004) emphasized the importance of studying mechanisms of aging separately in females and males (Table 2).

Table 2. Relative effect (% of change relative to control) of different gene manipulations in *Drosophila* females and males. With the exception of Cox7A where effects of gene mutation were examined for *D. simulans* all other data are for *D. melanogaster*

Gene	Function	Manipulation	Specificity	Trait	conditions	Females	Males

average effect of 3 replications, *two independent transgenes

Proximate causes of sex-specific variation in longevity, which are the fuel for natural and sexual selection in shaping ageing patterns across sexes, include, besides genetic variability, hormonally regulated differences in behaviour, metabolic and immune functions, as well as tolerance to oxidative and other stresses between females and males (May 2007). In addition, it is important to keep in mind that differential allocation of resources between longevity and reproduction also depend on developmental stage and environmental conditions (Boggs 2009).

3.1. Neuroendocrine Regulation of Ageing

Neuroendocrine system regulate interaction between nutrition, metabolism, reproduction and ageing and adjust organism behaviour and physiology according to developmental and ecological context. This system of regulation presumes complex network of large number of interdependent elements whose empirical investigation requires thorough biochemical analyses in each population/ species/environment arrangement. Among various signalling pathways and gene functions involved in ageing-pattern regulation, here we elaborate several mechanisms that were extensively explored in insects.

Insulin signalling pathways link longevity, oxidative stress resistance and immunity. In *Drosophila*, down-regulation of insulin/IGF-1 signalling in mutants or individuals with ablated medial neurosecretory neurons (MNSN) increases longevity due to changes in the level of secondary hormones - juvenile hormone and ecdysone (Tatar et al. 2003). These hormones affect many aspects of reproduction such as oogenesis and spermatogenesis, synthesis of vitellogenin and accessory gland proteins, courtship behaviour, expression of secondary sexual traits etc. (Gruntenko and Rauschenbach 2008; Ishimoto et al. 2009; Moczek 2009; Toivonen and Partridge 2009). As expected, mutations in insulin/IGF-1 signalling pathway affects females more strongly than males since their investment in reproduction is higher (Clancy et al. 2001; Tatar et al. 2001; Tu et al. 2002). Ablation of MNSN increased median lifespan by 10.5% in males, 18.5% in virgin and 33.5% in mated females (Broughton et al. 2005). Beside reduced fecundity, mated females with ablated MNSN, also show increased lipid and carbohydrate storage, increased resistance to starvation and oxidative stress and reduced tolerance to heat and cold. The observed effects of insuline/IGF-1 signalling pathway on ageing are associated with its influence on levels of expression of some genes. For example, down-regulation of this signalling pathway prevent phosphorylation of dFOXO transcription factor and enables its translocation to nucleus leading to increased transcription of genes such as those related to oxidative stress resistance and response to nutrient variation. On the other hand, overexpression of dFOXO increases lifespan (Hwangbo et al. 2004), while null mutants for *dFOXO* gene exhibit significantly shorter life-span in both females and males (Moskalev et al. 2011). The importance of dFOXO activity for determining ageing pattern has been described in many studies. This transcription factor is involved in hormetic response to some stresses (Jünger et al. 2003; Moskalev et al. 2011), and also, by its influence on transcription of other genes, such as suppression of *Lnk* gene, dFOXO is involved in regulation of insulin/IGF-1 signalling pathway (Slack et al. 2010). Homozygous mutants for *Lnk* gene have increased lifespan in females and males, but females are more resistant to starvation and oxidative stress, and accumulate more lipids and trehalose than males (Slack et al. 2010).

dFOXO transcription factor, together with p53, control the expression of stress signalling gene *D-GADD45*. Its ubiquitous overexpression is lethal (Peretz et al. 2007). However, in

nervous system it extends lifespan without reduction in fecundity and locomotor activity (Plyusnina et al. 2011). Moreover, fecundity was higher which might explain differences in the mutation effects on females and males (**Table 2**). Another example of gene expressed in nervous tissue, which differently affects female and male longevity, is *GLaz* gene involved in regulation of stress resistance and fat storage. Null mutants showed reduced longevity only in males and this sex-specific modulation of longevity is related to changes in protein homeostasis (Ruiz et al. 2011). Mutant flies also showed reduced fecundity, deficient courtship and lower mating success. On the other hand, mutation in the gene for olfactory receptor increases both lifespan and reproduction in females, as well as fat storage and oxidative stress resistance (Poon et al. 2010).

As mentioned previously, insuline-like pathways control juvenile hormone and ecdysone - two signalling molecules that were found to be significant for sex-specific development of ageing patterns. Juvenile hormone is a pro-ageing hormone known to suppress stress resistance and immunity (Flatt et al. 2005) and to mediate trade-off between reproduction and immune functions. Addition of methopren (juvenile hormone analog) in larval food increases early fecundity and decreases lifespan in *D. melanogaster* (Flatt and Kawecki 2007). Mutations in ecdysone receptor (EcR) are lethal in homozygotes while heterozygous mutants show increased longevity by 45% both in females and males (Simon et al. 2003). However, mutant females exhibit higher resistance to heat stress, while males become more resistant to oxidative stress and dry starvation. In one experiment where *Drosophila* populations were selected for postponed reproduction, it was found that young females have decreased levels of 20-OH-ecdysone, while in males activity of this hormone was unaffected by selection regime (Harshman 1999). Similarly, higher investment in reproduction in short winged cricket females was related to increase in 20-OH-ecdysone, whereas short- and long-winged males did not differ in the level of 20-OH-ecdysone (Zera et al. 2007).

Together with juvenile hormone and ecdysone, another product of neurosecretory neurons that is involved in regulation of reproduction and mating behaviour is dopamine neurotransmitter (Gruntenko and Rauschenbach 2008). In addition, it seems that dopamine system also has a great impact on shaping longevity. Namely, it has been found in natural *Drosophila* populations that polymorphism in Dopa decarboxylase, enzyme of the last step of dopamine synthesis, account for a large fraction of genetic variation in longevity (De Luca et al. 2003). As shown, the level of dopamine is negatively correlated with lifespan (Vermeulen et al. 2006a). However, in response to selection for short life-span increased dopamine level was recorded in females, while in males the same dopamine response was obtained in populations selected for long life-span.

3.2. Metabolic Differences between Sexes and Longevity Consequences

Reallocation of limited resources among different functions underlies longevity-reproduction trade-off. However, in many species this physiological trade-off may not be obvious or complete being that different functions may require qualitatively different compounds for their energy supply. For example, although short-winged morph of *Gryllus* allocates more resources to ovaries comparing to long-winged morph, there is negative correlation between tryglyceride and phospholipide accumulation since tryglycerides are main flight fuel while phospholipids are main component of oocytes (Zera 2005).

Furthermore, strategy of metabolite accumulation during preadult development and their usage during ageing may differ between sexes. In *Ceratitis capitata* females and males differ in the pattern of change in lipid content with age (Pujol-Lereis et al. 2012). In *D. melanogaster* lipid content increases with ageing while opposite trend was recorded in males (Vermeulen et al. 2006b). On the other hand, in species which do not feed at adult stages, all metabolites decrease during ageing (Lazarević et al. 2012).

QTL analysis on *D. melanogaster* documented that lipid storage is under control of sex-specific genetic mechanisms (De Luca et al. 2005). Comparisons among different *Drosophila* species demonstrated significant among-species differences in sexual dimorphism of metabolite pool content (Matzkin et al. 2009). As shown on *D. melanogaster*, males have, on average, more triacylglycerols than females (De Luca et al. 2005). Selection for postponed reproduction in the same species increased carbohydrate and lipid content in females, while in males only lipid content was increased (Djawdan 1996). In accordance with metabolite pool changes, both sexes in long-lived flies showed increased starvation resistance. However, only long-lived females were more resistant to desiccation comparing to control population (Djawdan 1998). In *Acanthoscelides obtectus*, on the other hand, selection for postponed reproduction and long life resulted in increased carbohydrate and lipid content in males, whereas in females only glycogen content was elevated (Lazarević et al. 2012). At the same time, selection for early reproduction and short life-span resulted in females with lower lipid and higher protein contents. Similar trade-off pattern was found for short-winged early-reproduction female crickets. Results of biochemical analyses on this species suggest that these changes are accompanied with alterations in activity of enzymes of intermediary metabolism (Zera 2005).

3.2.1. Nutritional Basis of Ageing

Studies on the nutritional basis of ageing revolve around positive effects of dietary restriction on life-span (Partridge et al. 2005; Piper and Partridge 2007) and the role of specific macronutrients and their ratio in shaping patterns of ageing and reproduction (Lee et al. 2008; Maklakov et al. 2008; Maklakov et al. 2009b; Simpson and Raubenheimer 2009). Generally, most studies have documented that two sexes differ in their sensitivity to diet quality and quantity.

Due to their higher investment in reproduction, it is expected that females are more responsive to nutritionally poor food than males (Nakagawa et al. 2012). Dietary restriction (40% dilution of sucrose-yeast medium) in Dahomey wild type virgin females of *Drosophila melanogaster* led to 60% increase in longevity while males lived only 30% longer (Magwere et al. 2004). However, when mated individuals of Canton S *Drosophila* line were fed on corn meal-sucrose-yeast medium, no sex differences were recorded (Min and Tatar 2006). Nutrient poor diet in *Tellegrylus commodus* did not affect male longevity while in females longevity was increased for about 60% (Zajitschek et al. 2009b). On the other hand, in *Telostylinus angusticollis*, both sexes elevated life-span for 65% on nutrient poor diet (Adler et al. 2013). Since life-extending effects could be achieved in female *D. melanogaster* without ovaries (Mair et al. 2004) it was suggested that reallocation of resources to reproduction is not the main cause of observed effects.

As stressed by Piper et al. (2011), exploring the effects of dietary balance is more informative than dietary dilution. Insects encountering imbalanced food can rebalance nutrient intake and utilization by behavioural and physiological mechanisms (Bede et al. 2007; Behmer

2009; Clissold et al. 2010). Higher consumption of nutritionally poor food has been described as compensatory response in many insects. However, in experiment of Min and Tatar (2006) males did not show compensatory response and females even increased intake of nutrient rich food. As for most other physiological processes, regulatory capacity, nutrient requirements and age-specific changes in nutrient needs may differ between the sexes. For example, behavioural adjustment to sex-specific dietary requirements could be achieved by sex-specific dietary preference. Female and male larvae of the gypsy moth in advanced instars differ in preference for lipids and proteins (Stockhoff 1993). When they were offered two complementary cubes of artificial diet, females chose to eat more proteins and males consume more lipids. This finding is in line with high energy demands in flying adult males, on one hand, and high investment of proteins in egg production in females, on the other hand. In cockroaches, males prefer carbohydrate biased food which increases their weight gain and lipid accumulation. In addition, this specific diet increases attractiveness and pheromone production in males implying that levels and courses of sexual selection may be largely influenced by dietary manipulations (South and al. 2011). Similarly, in *Telleogrylus commodus*, females prefer food with higher protein to carbohydrate ratio than males, which mirrors sex-specific difference in nutrient requirements for reproduction (Maklakov et al. 2008). However, in contrast to males, preferred food does not maximize reproduction in females implying that there might be intra-locus sexual conflict over nutrient regulation. Moreover, life-span and reproductive effort are maximized at different protein to carbohydrate ratios in females and males. In addition to the observed sex differences, Maklakov et al. (2008) also found that nutrient requirements for maximizing longevity differ from optimal nutrition for maximizing reproduction. In males, nutrient requirements for the two fitness components lay in the similar region of two-dimensional nutrient space, but in females, reproduction is maximized in much higher protein to carbohydrate ratio than longevity indicating that nutrient intake should make compromise between these two traits. Discrepancy in nutrient requirements between longevity and reproduction in females has also been recorded in *Drosophila melanogaster*, *Bactrocera tryoni*, *Anastrepha ludens* (reviewed in Simpson and Raubenheimer 2009) and explain shorter female life-span compared with males in these species. In difference to virgin males in the study of Maklakov et al. (2008), mated *T. commodus* males have different nutrient landscapes for longevity and reproductive effort (Archer 2012). It seems that, in presence of females, males have higher demands for proteins because of increased calling efforts, increased sperm production and production of spermatophore. When given a choice, mated males eat even more proteins than females. Geometric framework approach was also applied for studying effects of nutrient ratio on immune functions and it was shown that different functions (e.g., phenoloxidase and lysozyme activity) are maximized at different ratios of proteins and carbohydrates (Cotter et al. 2011).

Among genes that were found important for dietary restriction response (Banerjee et al. 2012) and fat metabolism (Reis et al. 2010) in insects, detail analysis was performed on protein deacetylase, sirtuin Sir2. Its overexpression in nervous system increased life-span more in females than males (Rogina and Helfand 2004). Overexpression of Sir2 in fat body provokes similar increase in longevity in both sexes, although sex-specific changes in transcriptional pattern of some genes were recorded (Hoffmann et al. 2013). The role of Sir2 in regulating longevity can be understood in the light of its effect on p53 transcriptional factor which is downstream target of Sir 2 (Bauer et al. 2009).

3.2.2. Stress Resistance and Life-Span

There is a significant overlap in gene expression patterns between stress response and ageing which point to involvement of stress resistance mechanisms in somatic maintenance (Vermeulen and Loeschke 2007). Besides, selection for extended longevity is often related to increased stress resistance (Wit et al. 2013).

Exposure to a stressor activates various protective responses in cells and organism which may act as anti-ageing agents (Demirović and Rattan 2013). This hypothesis is confirmed by various beneficial effects of mild stresses, i.e., “hormesis”, that were found in many animal species (see Rattan 2012). Hormetic effects, as other explained mechanisms involved in determination of life-span, were also shown to be sex-specific and dependent on dose and genetic background (Sarup and Loeschke 2011). Generally, hormesis has been documented more frequently in males than females (Minois 2000). Male longevity was increased for hypergravity and cold (Le Bourg et al. 2009), X-radiation (Vaiserman et al. 2003), and heat (Sørensen et al. 2007). On the other hand, female *D. melanogaster* needed higher doses of morphin chloride for life-extending effect (Dubiley et al. 2011).

In *Drosophila melanogaster*, females are more resistant to desiccation (Gibbs et al. 1997; Chippindale et al. 1998), starvation (Harshman et al. 1999; Le Bourg 2007a), oxidative stress (Le Bourg 2007b; Minois 2001; Moskalev et al. 2009), high temperature (Le Bourg 2007a), and cold stress (Norry and Loeschke 2002). On the other hand, they are more sensitive to the presence of galactose in food (Cui et al. 2004), hypergravity (Le Bourg et al. 2009), radiation (Vaiserman et al. 2003), fungus infection (Le Bourg 2009) and combined effects of the stresses (Le Bourg 2012). In *Drosophila buzzatti* selected for increased longevity, increased heat stress resistance was found only in females (Scannapieco et al. 2009).

Investigations on the mechanistic basis of ageing focus mostly on the relationship between longevity and oxidative stress resistance. Even under optimal conditions, metabolic functions are related to production of reactive oxygen species (ROS) in mitochondria which may damage macromolecules and accelerate ageing if they are not balanced with ROS scavenging and damage repair systems (Isaksson et al. 2011). Despite many experiments which have succeeded to confirm basic postulates of free radical / oxidative stress theory of ageing (e.g., Arking et al. 2000, 2002; Wang et al. 2004; Orr et al. 2005) there are also many of them which failed to find positive correlation between oxidative stress resistance and longevity (Bayne et al. 2005; Loder 2006), between ROS production and longevity (Miwa et al. 2004; Sanz et al. 2010) or between activity of antioxidative enzymes and oxidative stress resistance (Seto et al. 1990; Mockett et al. 2001). It appeared that antioxidative defence is more relevant for survival under stressful conditions than for natural variation in ageing and longevity (Le Bourg 2001; Haenold et al. 2005). It must be kept in mind that reactive oxygen species, besides their detrimental effects, also have crucial regulatory role in gene expression, cell signalling, differentiation and apoptosis (Sohal and Orr 2012). They are involved in immune defence and mediate trade-off between immune function and somatic growth as well as between immunity, sexual ornamentation and sperm quality (Dowling and Sommons 2009). Thus, it is not surprising that many studies have revealed duplicitous role of oxidative stress determined by dose dependence of positive or negative effects of many antioxidant and prooxidant chemicals (Bahadorani et al. 2008; Bakkali et al. 2008; Ernst et al. 2013; Lazarević et al. 2013).

Depending on stress intensity (i.e., dose) and species' life-history strategies, oxidative stress can mediate trade-off between longevity and reproduction either as a consequence of differential allocation of antioxidants between soma and reproductive tissues or due to higher

energy demands of increased reproductive effort (Monaghan et al. 2009). It is well known that oocytes accumulate antioxidant proteins such as superoxide dismutase, catalase, glutathione S transferase, yolk proteins (Kurama et al. 1995; Collins et al. 2004; Freitas et al. 2007; Diaz-Albiter et al. 2011) which can be used for defence against oxidative challenge (Seehus et al. 2006; Schneider et al. 2011). In an experiment on *A. obtectus*, Lazarević et al. (2013) have found hormetic effect of low concentration of Paraquat (PQ) pro-oxidant agent on base line mortality of females selected for early reproduction and short life-span. Authors hypothesized that early-life hormesis was a consequence of higher egg load and, accordingly, increased content of yolk proteins known to serve as ROS scavenger in PQ challenged insects (Seehus et al. 2006) and be involved in regulation of iron homeostasis and antioxidative defence (Nichol et al. 2002; Pham and Winzerling 2010; Geiser and Winzerling 2012).

In experiment on *Gryllodes sigillatus*, Archer et al. (2012a, 2012b) determined calling effort in males and egg production in females as measures of investment to reproduction, similarly to other experiments with crickets (Hunt et al. 2006; Maklakov et al. 2008; Zajitschek et al. 2009a, 2009b), in order to explore the relationship between oxidative stress and longevity and reproduction. First, they found divergent reproductive strategies between sexes: females maximize reproductive output early in life, while males continually increase calling during ageing. Then, genetic correlations between life history traits and levels of oxidative damage (protein carbonyls) and levels of antioxidative defence (total antioxidative capacity) were determined. As expected, shorter lived sex (females) had higher level of damaged proteins. In both sexes, protein damage was positively correlated with baseline mortality and negatively correlated with life-span and early reproduction. In both sexes, increased damage is followed by increase in antioxidative capacity (positive genetic correlations). However, in contrast to males, late-life protein damage which affected life-span, ageing rate and antioxidative capacity, were not correlated with reproductive effort in females. These results, together with positive genetic correlations across sexes for the level of oxidative damage and antioxidative protection, suggest that sexes differ in managing their redox states and that intra-locus sexual conflict constrained their evolution towards optimal values.

Despite the known importance of mechanisms which repair or remove oxidatively damaged macromolecules, data on sexual dimorphism in these systems are scarce (Østergaard Hansen et al. 2012). Effects of selection for increased longevity and effects of genetic manipulations on the expression of genes for heat shock proteins were mostly studied in males (Kurapati et al. 2000; Tower 2010). Overexpression of Hsp proteins showed some fitness cost (Silberman and Tatar 2000) and effects depended on the tissue and developmental stage (reviewed in Hughes and Reynolds 2005). During ageing Hsp22-GFP and Hsp70-GFP reporters are up-regulated slightly more in males than females and more in muscle and nervous tissues (Tower et al. 2013). Mutations in *Hsp* genes have detrimental effects more to female than male longevity and diminishes female ability to survive under oxidative stress comparing to control flies (Moskalev et al. 2009). Under control conditions, mutations in genes for transcription factors for heat-shock proteins affects more female than male longevity and some of the mutations showed hormetic effect more often in females than males (Moskalev et al. 2009).

In *D. melanogaster*, activity of superoxide dismutase affects female longevity more than male's and positive effects of SOD overexpression was detected in more genetic backgrounds (Spencer et al. 2003). In *Acanthoscelides obtectus* females (longer lived sex) have higher level of catalase activity (Šešljija et al. 1999). In non-virgin *D. simulans*, females (shorter lived sex)

have higher production of hydrogen peroxide, lower activity of catalase and mitochondrial SOD, higher proton leak, ADP: O ratio and mtDNA density (Ballard et al. 2007). Since mating is energetically more costly to females, it may be expected that they are more capable to increase metabolic activity in response to reproduction.

3.2.3. The Roles of Mitochondria

Since mitochondria are major generator and target of intracellular ROS, they are suggested to play central role in the ageing process. Age-related decline in mitochondrial function, as well as life-extending effects of mitochondria-targeted genetic and environmental manipulations, demonstrate important role of mitochondria in longevity determination (reviewed in Morrow and Tanguay 2008 and Bratić and Trifunović 2010).

It is well known that functioning of the cell depends on communication between nucleus and mitochondria which, according to direct and retrograde signals, enables adjustment of metabolic reactions with energy requirements. Impairment of mitochondrial function, due to exposure to stress or lack of co-adaptation between nuclear and mitochondrial genomes, decreases ATP production, increases free radical leak and activate regulatory mechanisms which may lead either towards increased expression of respiratory complexes or towards apoptosis (Lane 2011). Outcome will depend on the apoptotic threshold level. Low threshold is related to good mito-nuclear match, low fertility and delayed ageing. As was shown in *Drosophila*, production of reactive oxygen species is lower in long-lived than short-lived lines (Driver and Tawadros 2000) and in females than males (Vina et al. 2003). Additionally, mitochondria-targeted antioxidants show sex-specific effects on longevity of *D. melanogaster* (Magwere et al. 2006; Krementsova et al. 2012)

It has been suggested that maternal inheritance of mitochondria contributes to sexual dimorphism in ageing and longevity by promoting higher co-adaptation of mitochondrial and nuclear genome in female sex (Zeh and Zeh 2005; Rand 2005; Tower 2006; Wolf and Gemmell 2012). On the other hand, it attenuates the strength of selection on male mitochondrial genome leading to increased mutation load and greater mitochondrial genetic variance for male than female longevity and ageing rate (Gemmell et al. 2004; Camus et al. 2012). In *D. melanogaster*, these mutations affect nuclear gene expression only in males modifying nearly 10% of transcripts mostly in reproductive tissues (Innocenti et al. 2011). As a consequences of asymmetric inheritance of mitochondrial genome, natural and sexually antagonistic selection can maintain mutations highly deleterious to males if they are beneficial to females, or if nuclear genome harbours modifiers which diminish their negative effects. The consequence of the disruption of mito-nuclear interactions may also be revealed as a change in gene expression pattern which lead to increased longevity (Rand et al. 2006).

Several genetic elements, which were mentioned earlier as important elements in regulating life-span, have also been found to have roles in controlling mitochondrial metabolism. Among other functions, transcription factor p53 is involved in regulation of apoptosis and exhibits antagonistic pleiotropic effects on longevity depending on age and sex (Shen and Tower 2010). Interestingly, sexual dimorphism of p53 effects is under the control of FOXO, while the level of the effects depends on Sir2 gene. Additionally, the mechanisms by which p53 exerts longevity effects might overlap with regulatory pathways which determine feeding behaviour and nutrient utilization.

ABSTRACT

During mating, male bush-crickets transfer a complex spermatophore to the female. The spermatophore is comprised of a large nuptial gift which the female consumes while the sperm from the ejaculate-containing ampulla are transferred into her. Two main functions of the nuptial gift have been proposed: the ejaculate protection hypothesis and the parental investment hypothesis. The former, founded on sexual selection theory, predicts that the time to consume the gift is no longer than necessary to allow for full ejaculate transfer. The latter maintains that gift nutrients increase the fitness or quantity of offspring and hence the gift is likely to be larger than is necessary for complete sperm transfer. With an aim to better understanding the primary function of nuptial gifts, we examined sperm transfer data from field populations of five *Poecilimon* bush-cricket taxa with varying spermatophore sizes. In the species with the largest spermatophore, the gift was four times larger than necessary to allow for complete sperm transfer and is thus likely to function as paternal investment. Species with medium and small gifts were respectively sufficient and insufficient to allow complete sperm transfer and are likely to represent, to various degrees, ejaculate protection. We also found that species that produce larger

* Corresponding Author's Email: J.McCartney@massey.ac.nz.

spermatophores transfer greater proportions of available sperm than species producing smaller spermatophores, and thus achieve higher paternal assurance.

Keywords: ejaculate protection, mating effort, paternal investment, spermatophore size, sperm transfer, sperm competition

INTRODUCTION

Nuptial feeding has been observed in several insect taxa (Thornhill and Alcock, 1983; Vahed, 1998). Male bush-crickets (Tettigoniidae) transfer a substantial, and often costly, spermatophore to the females for consumption during mating (Wedell, 1994a, 1994b; Vahed, 2007a). The spermatophore consists of an ampulla that contains the sperm, and a spermatophylax that, in most species, is a large gelatinous mass. The female first eats the spermatophylax and then eats the smaller ampulla along with any remaining sperm and seminal fluid (Bowen *et al.*, 1984). There is debate over the selective pressures that maintain nuptial gift size in bush-crickets (for reviews see Thornhill and Alcock, 1983; Simmons and Parker, 1989; Vahed, 1998; Gwynne, 2001; Vahed, 2007; Gwynne, 2008; McCartney, *et al.* 2008, 2010, 2012). Despite recent discussions concerning the effect of sexual conflict on nuptial gift size (e.g., Vahed, 2007b; Gwynne, 2008; Lehman, 2012) two hypotheses remain central to understanding the role of gift size: the ejaculate protection hypothesis and the parental investment hypothesis.

The ejaculate protection hypothesis argues that the nuptial gift is sexually selected; it increases fertilisation success by diverting the female away from the sperm ampulla while maximum insemination is achieved (Gerhard, 1913; Boldyrev, 1915; Gwynne, 1984; Sakaluk and Eggert, 1996; Vahed and Gilbert, 1996; Simmons, 2001). The parental investment hypothesis proposes that the function of the nuptial gift is derived from its nutritive value and that these nutrients are passed into the donating males' offspring; the gift is thus under natural selection to increase the quality and/or the quantity of the male's offspring (Trivers, 1972; Thornhill, 1976; Gwynne, 1986, 1988a, 1988b, 1990; Reinhold, 1999).

The ejaculate protection and paternal investment hypotheses are not mutually exclusive (Quinn and Sakaluk, 1986) and present research focuses on the relative importance of the two hypotheses in different taxa. It is likely that the spermatophylax evolved through sexual selection for ejaculate protection in bush-crickets (Gwynne, 1986, 1990, 1997, 2001), but there is evidence that both functions can be involved in the maintenance of spermatophylax size in various tettigoniid species (for reviews see Vahed, 1998; Gwynne, 2001; McCartney *et al.* 2008).

Nuptial gifts that function to protect the ejaculate are predicted to be smaller, less nutritious, and of a size that co-varies with either sperm number and/or ampulla size and should be no larger than necessary to allow for complete insemination (Reinhold and Heller, 1993; Wedell, 1993a, 1994a, 1994b; Heller and Reinhold, 1994; Vahed and Gilbert, 1996). Nuptial gifts that are influenced by paternal investment are likely to be large, nutritious (Wedell, 1994a, 1994b), and take longer to consume than it takes to transfer a full complement of sperm (Wedell, 1994b). While it can be relatively simple to test the prediction of the ejaculate protection hypothesis, at least three further criteria underpin paternal investment in nuptial-gift-bearing species and are needed to distinguish it from the ejaculate protection hypothesis: 1) the

degree of last-male mating advantage; 2) the time that it takes for the nutrients of the spermatophylax to directly affect the donating males' offspring; and 3) the relationship between female mating interval and egg laying interval (see Vahed, 1998 and references cited therein).

The ejaculate protection hypothesis is supported by comparative studies across taxa showing positive correlations between spermatophylax size and ampulla mass or sperm number (Wedell, 1993a; Vahed and Gilbert, 1996; McCartney *et al.*, 2008, 2012), as well as studies within species showing that the size of the nuptial gift or the consumption time of the gift is roughly similar to the time that it takes for the majority of sperm to transfer into the female (e.g., Wedell and Arak, 1989; Wedell, 1991; Reinhold and Heller, 1993; Heller and Reinhold, 1994; Vahed, 1994; Simmons, 1995a). Evidence of paternal investment has also been observed in some species (Gwynne *et al.*, 1984; Gwynne, 1986, 1988a, 1988b; Simmons, 1990; Wedell, 1994a, 1994b; Simmons *et al.*, 1999; Reinhold, 1999), yet almost all insect species studied thus far, including those with properties of paternal investment, have nuptial gifts (or nuptial gift consumption times) that approximate the size necessary for complete sperm transfer (Heller and Reinhold, 1994; Simmons, 1995a; Simmons and Gwynne, 1991; Vahed, 1994), and are therefore likely to be maintained primarily through sexual selection via the ejaculate protection hypothesis (Vahed, 1998). Diverse examples of this rule can be found in Mecoptera as prey and salivary masses, Diptera as nuptial prey and regurgitated food, Coleoptera and Zoraptera as cephalic gland secretions, and other Orthoptera, as hind-wing and glandular secretion feeding (Vahed, 1998 and references cited therein).

Possibly the only exception is *Requena verticalis*, initially reported to have a spermatophylax twice as large as necessary to allow for complete sperm transfer of the ampulla (Gwynne *et al.*, 1984; Gwynne, 1986, 1988b). However, further research on this species (Simmons, 1995a, 1995b; Simmons *et al.*, 1999) and different interpretations of what constitutes 'complete' sperm transfer (Vahed, 1994, 1998; Simmons, 1995a) suggest that complete sperm transfer may not be achieved until close to, or even after gift consumption (Vahed, 1998). Additionally, males have a substantial first-male paternity advantage (Gwynne, 1988b; Simmons and Achmann, 2000; Simmons *et al.*, 2007) and variable spermatophylax sizes, perhaps as a result of variability in female availability, re-mating interval (Simmons, 1995b), and sexual status (Simmons *et al.*, 1993). At times, therefore, gift size approximates the size necessary for complete sperm transfer.

In order to better understand the relationship between nuptial gift size and sperm transfer pattern and the selective pressure that most influences its variation, there is perhaps no better model than the bush-cricket genus *Poecilimon* (Tettigoniidae) (McCartney *et al.* 2008, 2012). This genus contains species with a large diversity in mating behaviours. Comparisons among species within genera can be particularly useful as characters shared by congeners are often held constant and thus control to a large degree for similarities that may be caused by relatedness (Harvey, 1991; Harvey and Pagel, 1991). With around 140 described *Poecilimon* species (Eades and Otte, 2008), the variation in nuptial gift size is unmatched among Orthoptera and approaches the magnitude of family-wide variation (McCartney *et al.*, 2008), with spermatophore size varying from 6.1% (*Poecilimon laevissimus*) to 37% (*P. thessalicus*) of the relative body mass of the male (McCartney *et al.*, 2008). This clearly represents large variation in male reproductive investment.

Few bush-cricket studies have investigated nuptial gift function from a sperm transfer perspective and, of these most have used laboratory-reared individuals despite concerns about the validity of this approach (see McCartney *et al.*, 2008 for discussion). Even fewer studies

still, have considered sperm transfer patterns within field populations (eg. Heller & von Helversen, 1991; Reinhold, 1994; Vahed and Gilbert, 1996). Furthermore, interpretation of data has been complicated by the diversity of taxa involved; variations in sperm transfer may ultimately be linked to taxon differences and not nuptial gift size *per se* (for discussion see Gwynne, 1995; Vahed and Gilbert, 1996; McCartney, 2010).

Our aim here was to better understand the premise that nuptial gift size relates to function. First, in order to assess the match between nuptial gift consumption time and optimum sperm transfer time across closely related species with marked variation in nuptial size, we combined published sperm transfer and nuptial gift consumption time data from two field-observed *Poecilimon* taxa that produce medium and large gifts (Reinhold and Heller, 1993, Heller & Reinhold, 1994), with sperm transfer and gift consumption data from three novel field-observed *Poecilimon* species; two with small gifts and one with very large gifts. A close match between gift consumption and sperm transfer would be consistent with the sperm protection hypothesis, whereas if complete sperm transfer occurs long before spermatophylax gift consumption is completed, we have grounds to infer a paternal investment function. Secondly, we controlled for body mass and relatedness, and compared spermatophore size between species to the proportion of sperm that has transferred into the female by the time she has consumed the spermatophore. A significant relationship would indicate that males of *Poecilimon* taxa that produce larger spermatophores have increased confidence of sperm transfer, and thus paternal assurance, compared to taxa producing smaller spermatophores.

MATERIALS AND METHODS

Species and Sites

Poecilimon is a genus of bush-crickets (Phaneropterinae, tribe Barbistini) (Orthoptera: Ensifera: Tettigoniidae), with about 65 European species that are mostly situated in the east Mediterranean (Heller, 2004). Three species, *Poecilimon laevisissimus* (Fischer, 1853), *P. erimanthos* Willemse and Heller, 1992, and *P. thessalicus* Brunner von Wattenwyl, 1891, were chosen to represent the genus in this study, as a previous study found that these species had some of the largest differences in relative spermatophore size and sperm number within the genus (McCartney *et al.*, 2008). The spermatophore sizes of *P. laevisissimus* and *P. thessalicus* represent the upper and lower limits, with *P. erimanthos* producing a small to medium-sized spermatophore of 7.2% relative mass (McCartney *et al.*, 2008). Sperm number from single matings range between 90,000 and 140,000 - 210,000 for *P. laevisissimus* and *P. erimanthos* respectively, and up to about 14,500,000 in *P. thessalicus* (McCartney *et al.*, 2008). Data for two further species, *P. v. minor* and *P. v. veluchianus* were obtained from the literature because these species represent medium to large-size spermatophores and sperm numbers respectively (Reinhold and Heller, 1993, Heller & Reinhold, 1994). All species examined here are nocturnal except *P. erimanthos* which is diurnal and mates during the day.

Any important differences between the methods used on the novel species presented here, *P. laevisissimus*, *P. erimanthos* and *P. thessalicus*, and previously published species, *P. v. veluchianus* and *P. v. minor*, are outlined below. However, see Reinhold and Heller (1993) and Heller and Reinhold (1994) for detailed methods on *P. v. veluchianus* and *P. v. minor*.

Fieldwork on all novel species was carried out during the summers of 1990, 1997 and 1998 on the Peloponnese Peninsula and mainland Greece. *Poecilimon erimanthos* and *P. laevisissimus* were observed at Erimanthos Valley (east of the village of Kumani, N. Elia, 37°46'N, 21°47'E.), and *P. thessalicus* at a site inland from Katerini (north-west of the village of Elatochori, 40°19'N, 22°15'E). Both sites were semi-pastoral with forest margins, and population borders were demarcated by roads, forests or cliffs.

Spermatophore Consumption Time, Male Body Mass and Spermatophore Mass

All measurements on spermatophore consumption of novel species were taken from field observations of marked (*P. erimanthos*) or non marked animals (*P. laevisissimus* and *P. thessalicus*) throughout their mating season. Captured animals were paired in containers or hanging mesh cages in the field. Male and female *P. laevisissimus* were captured as sub-adults and allowed to mature for around seven days before pairing to allow for full development of the accessory glands (males) and full receptivity (Heller and Helversen, 1991; see Reinhold & Heller, 1993; McCartney *et al.*, 2008 for discussion on cage and laboratory effects in *Poecilimon*). To minimize disturbance of females, observations of spermatophore consumption progress were made at intervals rather than continuously. *Poecilimon laevisissimus* and *P. thessalicus* were only used in observations after witnessing the onset of spermatophore consumption, whereas we estimated onset for *P. erimanthos* as half of the interval between the first observation of a female without a spermatophore, and again with a spermatophore (females observed about every hour). Spermatophore consumption times of all species were also estimated as half of the interval between the observation of the female last seen with a spermatophore, and subsequently without a spermatophore.

Spermatophore consumption time and male body mass were measured in the 1997 and 1998 breeding seasons and pooled for *P. thessalicus* (data did not differ significantly between years; spermatophore consumption time, $t_{14} = -0.561$; $p = 0.584$; male body mass $t_{66} = -1.501$; $p = 0.138$). Spermatophore masses for *P. thessalicus* are reported from 1998. Measurements of spermatophore consumption time, male body mass and spermatophore mass for *P. laevisissimus* are reported from 1997. Spermatophore consumption times were recorded for *P. erimanthos* in 1990 and the male body mass and spermatophore mass were recorded in 1997.

Sperm Transfer

Poecilimon thessalicus and *P. laevisissimus* were observed in 1998 whereas *P. erimanthos* was observed in 1997 and 1998. *Poecilimon erimanthos* (in 1997) and *P. thessalicus* (in 1998) were observed at the locations where they were collected. In 1998, we collected approximately 50 sub-adult *P. laevisissimus* and *P. erimanthos* east of the village of Kumani, N. Elia and took them to Central Greece, where we made further caged observations.

All bush-crickets taken from the field were sub-adults and were stored separately by sex and species, then allowed to mature for at least seven days. We allowed mating of 20 to 30 virgin pairs of each species. Mated females were allocated randomly to predetermined spermatophore attachment times that were set at intervals relative to the spermatophore

consumption time in order to determine the rate of sperm transfer. For each species, the duration of the first sperm transfer trial was set to equal the average spermatophore consumption time for that species (see Table 1). All mated females, except some *P. erimanthos* in 1997, were assigned randomly to a pre-determined transfer time for examination. For *P. laevisissimus* and *P. thessalicus* we tested sperm transfer times at appropriately equal periods either side of the average spermatophore consumption time, and repeated this until we had adequately covered the full period from no transfer until (near) full transfer (*P. thessalicus* = 120, 240, 480, 780, 1020, 1260 min intervals, *P. laevisissimus* = 60, 120, 180, 240 min. intervals). The spermatophores of *P. erimanthos* in 1997 were removed at various intervals between 30-80 min., with two distinct modes of 35 min and 75 min. This meant the mean number of sperm that had transfer in six observations between 30-35 min., and six observations between 45-80 min. were pooled into two groups at 35 min. and 80 min. and the mean sperm transfer value was used for each. The spermatophores of *Poecilimon erimanthos* in 1998 were removed at 1 min., 120 min., and 240 min and combined with the data of 1997 (35 min. and 80 min.).

Immediately after mating, each female was placed head-first into a large scintillation tube to prevent her from bending to remove the ampulla. We then stored the females in a cool, shaded area and males were returned to cages. After the assigned period, each female was removed from her vial and the spermatophore removed by grasping the ampulla at its base with dissecting forceps and pulling it carefully from her genital pore and the spermatheca was excised. The female was killed and the spermatheca and the ampulla were stored in separate vials with a known volume of water for sperm counting (1-5 ml depending on the structure's size). If sperm ampullae became semi-detached or sperm had drained outside the female these data were not used in the analysis.

Each ampulla and spermatheca was macerated with a scalpel and mixed by passing it repeatedly through a syringe until the sperm had been suspended in the water and the sample homogenised. A sub-sample was placed on a haemocytometer slide (Swift: Neubauer improved). Sperm from a minimum volume of 50 μ l (or up to 200 μ l) were counted and multiplied by the appropriate dilution factor to give the total number of sperm per spermatheca. Five sub-samples were taken and the solution was remixed before each new sub-sample was taken. From total sperm (ampulla and spermatheca) we derived the percentage of sperm within each mating transferred from the spermatophore into the spermatheca.

ANALYSIS

Sperm Transfer and Spermatophore Consumption

In order to compare the match/mismatch of complete sperm transfer and spermatophore consumption of all novel species, average spermatophore consumption times of all species were overlaid on a time-course chart of sperm transfer. In an attempt to compare the sperm transfer profiles of the three species presented here we spent considerable effort fitting regression models to sperm transfer patterns, and were not convinced that they could either reliably resolve the shape of sperm transfer curves, or validly explain the behaviour of sperm transferring into the female. Ultimately, no model we used could clarify the sperm transfer relationship between different species (see

In each species there were mating attempts resulting in no sperm transferring. These data were not included in analyses but are discussed further. Data were analysed using SAS 9.1. The analyses of *P. v. veluchianus* and *P. v. minor* were as recorded in Reinhold and Heller (1993) and Heller and Reinhold (1994).

Regression analyses on relative spermatophore mass against the proportion of sperm that had transferred into the female were first performed across taxa. All proportion data were arcsine (square root) transformed and tested for normality. In conjunction with this regression analysis, corresponding regression analyses were also performed on transformed proportion data with phylogenetic independent contrasts in order to control for relatedness (Felsenstein, 1985). While this method is typically preferred over standard linear regression analyses across species, sample sizes are reduced further using contrasts (n-1) and so have less power.

Phylogenetic Independent Comparisons

A cladogram of the species used in this study was constructed using the literature on the phylogeny for these *Poecilimon* taxa (see Figure 1 for references) and the computer package PDAP (Maddison & Maddison, 2006) (Figure 1). The proportion of sperm and relative spermatophylax data were added to the tree in order to calculate phylogenetically-independent contrasts. In all cases, branch lengths were set to 1. The contrasts were then standardised by dividing them by the variance (square root of the sum of the branch length, Felsenstein (1985)). Generalised linear models were then used to regress the standardised independent contrasts of

relative spermatophore size against the standardised independent contrasts of the proportion of transferred sperm response variable. All inferential regressions involving phylogenetically-independent contrasts were forced through the origin (Garland *et al.* 1992).

RESULTS

Spermatophore Consumption and Sperm Transfer

The spermatophores (spermatophylax and ampulla) were consumed in 101 ± 10.7 min (range 30-165 min., $n = 14$) for *P. laevissimus* (Table 1), a period too short to allow more than a small portion of the sperm to transfer into the female (Figure 2). Only about 15% of available sperm had transferred during any of the observations made prior to the last observations at 240 min (2.4 times longer than the mean spermatophore consumption period). The four observations at this longest interval revealed that a large amount of sperm still remaining in the ampulla and therefore the spermatophylax appears to be much smaller than is necessary to ensure complete sperm transfer.

Spermatophores in *P. erimanthos* (1990) were consumed in 84 ± 3.5 min (range 55-130 min, $n=39$, Table 1). This corresponds with a peak in sperm transfer, and more than 50% of sperm had transferred to the spermatheca by this time (Figure 2). After the time usually required for spermatophore consumption, sperm transfer seemed to slow down reaching about 75% of the total transfer after 240 min. Thirty five minutes after mating no sperm had been transferred ($n=9$) yet after this time all except one female (that was discarded because she was found with no sperm after 4 hours) contained over 50% ($n=18$) of the available sperm. So a fast transfer process occurs in this species and takes between 35 and 60 min, and is complete just before the spermatophore is normally consumed, indicating that the spermatophore may be of about the correct size for optimum sperm transfer (about 60% of total sperm).

Pooled data for *P. thessalicus* from both years gave a spermatophore consumption time of 15.7 h (943 ± 47.6 min, $n=16$) (Table 1). The sperm transfer pattern of *P. thessalicus* differs from that in the two previous species, in that peak transfer occurred between 13-25% of mean spermatophore consumption time (240 min., Figure 2), and 93% of sperm had transferred by the end of spermatophore consumption. There was a clear plateau in sperm transfer in *P. thessalicus* at around 90-95% of total available sperm and therefore females were inseminated nearly four times more quickly than required for spermatophylax consumption. Even the fastest spermatophore consumption, of about 710 min, would have allowed around 93% of the sperm to transfer by the time one third of the spermatophore was consumed. Five out of 26 matings (19.2%) did not release any sperm into the female after transfer onset (one female at each of 240, 780, and 1260 min and two females at 480 min) and, since all other pairings resulted in close to, or above, 90% sperm transfer, these were not included in calculations of the means or standard errors. Interestingly, the average number of sperm in the ampullae that failed to transfer any sperm was only 8.3 million ($n=5$, S.E.=2.9 million, range = 2.3-17.8 million), significantly fewer than the 22.6 million ($n=22$, S.E.=21 million, range = 0.05-37.3) in spermatophores that did transfer (Mann-Whitney rank analysis $U=27$, $P < 0.007$).

Table 1. Male body mass, spermatophore consumption time (min) and absolute and relative spermatophore mass in three species of *Poecilimon* studied here (mean $\pm$ S.E. (range: n); upper three rows) and two sub species taken from Reinhold & Heller (1993), (lower two rows)

Species	Spermatophore consumption time (min) (range: n)	Spermatophore mass (mg)	Male body mass (mg)	Relative spermatophore size
<i>P. erimanthos</i>	84 $\pm$ 3.5 (55-135: 39)	47 $\pm$ 3 (n=11)	640 $\pm$ 4 (n=25)	7.2% (n=11)*
<i>P. laevisissimus</i>	101 $\pm$ 10.7 (30-165:14)	47 $\pm$ 6 (n=9)	781 $\pm$ 13 (n=50)	6.1% (n=9)*
<i>P. thessalicus</i>	943 $\pm$ 47.6 (710-1380: 16)	112 $\pm$ 8 (n=28)	440 $\pm$ 7 (n=68)	33% $\pm$ 2..34% (n=17)
<i>P. veluchianus veluchianus</i>	570	162	640	24.9%
<i>P. v. minor</i>	200	74	365	19.1%

*No S.E. available because relative spermatophore mass was taken from dividing the average of pooled spermatophore mass from the average of pooled male body mass.

Figure 2. Percentage of sperm transferred after copulation from the male ampulla to the female spermatheca ($\pm$ S.E.) plotted relative to the mean spermatophore consumption time, (numbers above points = n). Novel species are represented by unbroken lines: *P. laevisissimus* (open circles), *P. erimanthos* (grey circles), and *P. thessalicus* (black circles). Broken lines represent *P. v. veluchianus* (closed squares) and *P. v. minor* (open squares) calculated from the published data (S.E and n not presented; for details see Heller and Reinhold (1994)). Dashed vertical lines show one SD in consumption time for *P. thessalicus* (the species with the largest SD).

Relative Spermatophore Mass and Proportion of Sperm Transferred

No significant relationship was found between spermatophore size and the proportion of sperm that had transferred into the female by the spermatophore consumption time ($F_{1,4} = 7.69$, $p = 0.069$, $r^2 = 0.72$). While this was not strengthened while controlling for relatedness ($F_{1,3} = 3.06$, $p = 0.179$), a strong relationship is apparent (Figure 3). An increase in sample size is likely to produce a significant effect; males of larger spermatophore-producing *Poecilimon* taxa are likely to transfer a greater proportion of sperm than species producing smaller spermatophores.

Figure 3. Spermatophore size compared to the proportion of sperm that have transferred into the female at the time of spermatophore consumption among five *Poecilimon* taxa. NB. Data are arcsine (square root) transformed.

DISCUSSION

The percentage of sperm that had transferred into the female by the time it took her to consume and remove the spermatophore differed markedly between the five species. The match/mismatch between complete sperm transfer and spermatophore consumption time found across our species correspond to our predictions that nuptial gifts of different sizes are affected by ejaculate protection and paternal investment to different degrees. Large nuptial gifts in *Poecilimon* are apparently either of correct size or larger than necessary to allow for a full transfer of sperm, whereas small nuptial gifts seem to be less than capable of protecting the ejaculate and allowing the complete complement of sperm to be transferred. Sexual selection for larger spermatophores in *Poecilimon* is likely to increase male confidence in sperm transfer (McCartney *et al.*, 2008, 2010) and correspond to greater level of courtship related female mating investment (McCartney *et al.*, 2012).

Poecilimon laevis and *P. erimanthos* have small spermatophylaxes which seem to be either smaller than necessary for sperm transfer, or have consumption times marginally correspondent with the time it takes for sperm to transfer into the female; thus they are likely to function primarily as ejaculate protection. *Poecilimon thessalicus*, on the other hand, has one of the largest spermatophores reported (McCartney *et al.*, 2008), and a nuptial gift almost four times larger than necessary for complete sperm transfer. It is therefore likely to function as both ejaculate protection and paternal investment.

It may be assumed that *Poecilimon* species with a similarly large spermatophore size as *P. thessalicus* will also have similarly long consumption times. This, however, does not appear to be the case in either of the subspecies of *P. veluchianus* which also have large nuptial gifts but comparatively quick consumption times (Table 1, Figure 2). While *P. thessalicus* and *P. veluchianus* indeed have larger gifts, the difference does not seem to lie in the speed at which

the sperm transfers into the female, but rather with the extended period over which female *P. thessalicus* consume nuptial gifts. This point is important when understanding a key assumption of the paternal investment hypothesis; males must invest in their own offspring. Lengthened consumption time increases ejaculate transfer which delays the speed at which a female remates and increases the time in which nutrients of the donating male's gift can be incorporated in his offspring. Reasons for an extended feeding time in *P. thessalicus* are thus far unknown, however the study population was at relatively high altitude (ca. 1,100 m a.s.l.), with night time temperature often at around 10-15°C, compared to *P. v. veluchianus* and *P. v. minor* (330 m a.s.l.; Reinhold and Heller, 1993) and *P. erimanthos* and *P. laevissimus* (around 600 m a.s.l.) where night temperatures are typically 20°C or above (unpubl. data). The metabolism of *P. thessalicus* at these temperatures is likely to be lower than that of the other species, resulting in consumption duration and digestion times of nuptials gift being significantly slower. However, temperature differences are unlikely to have affected our results because spermatophores are costly to produce and are evolutionary labile (McCartney *et al.*, 2008); males would be expected to allocate fewer resources to gift production – to a size more appropriate to ejaculate protection – if there were no fitness benefits to having a proportionately large spermatophylax gift. A further explanation for the slow gift consumption time of *P. thessalicus* may be related to possible bitter substances in the spermatophylax of *P. thessalicus*. These may affect the speed at which females are able to consume the nuptial gift (as suggested by Heller *et al.*, 1998) but further work is needed in order to verify the substances, their palatability, and the effect they have on females.

While there is a match between nuptial gift consumption and sperm transfer times in *P. v. veluchianus* and *P. veluchianus minor* these species have nuptial gift sizes that further correspond to our predictions that larger gifts are influenced by paternal investment. *Poecilimon v. veluchianus* has a substantial last male mating advantage (Achmann *et al.*, 1992) and nutrients from the nuptial gift of the donating male are likely invested into his own offspring (McCartney 2010). Evidence of paternal investment in this species comes from a correlation of nuptial gift size on the dry mass of the donating males' offspring, and a greater lifespan of starved offspring (immediately after eclosion) fathered by males with large spermatophores (Reinhold, 1999).

Typically it takes 3-4 days for the nutrients in nuptial gifts to be incorporated in egg batches in the female (Bowen *et al.*, 1984; Gwynne and Brown, 1994; Wedell, 1993b; Simmons and Gwynne, 1993; Reinhold, 1999, although see Voigt *et al.*, 2006, 2008). While sperm precedence patterns have only been analysed in two *Poecilimon* species (*P. veluchianus*; Achmann *et al.*, 1992 and *Poecilimon hoelzeli*; Achmann, 1996), both show a last male mating advantage. The combination of these factors in both *P. erimanthos* and *P. laevissimus* is, however, likely to exclude the possibility of paternal investment; both species remate, on average, every 1-2 days and lay eggs every two days (McCartney 2010). It is therefore unlikely that there is sufficient time for gift nutrients to be incorporated into the donating male's offspring. In contrast, field observations from *P. thessalicus* suggest that females may have extended inter-mating refractory periods of about 7-8 days (and up to 19 days) and lay eggs every 1-2 days (McCartney, 2010), so males are likely to have their nutrients incorporated into the majority of eggs before females remate.

Transfer of a full ejaculate is necessary to ensure optimum fertilisation for males especially in polyandrous species (Smith, 1984). It is difficult therefore to understand why, in the two species that produce smaller spermatophores, males do not protect their ejaculate with larger

nuptial gifts. In *P. erimanthos* and *P. laevisissimus* females consumed 48% and 87% respectively of the sperm that males produced. While *P. laevisissimus* seemed to remove and eat the spermatophore nearly eight times faster than expected for maximum sperm transfer, sperm from *P. erimanthos* transferred into the female at a rate that arguably approximated spermatophore consumption time, but still resulted in a waste of a large portion of sperm. Similarly, 9% of spermatophores are estimated to be prematurely consumed in *P. v. veluchianus* (Reinhold and Heller, 1993). It is likely that there is conflict between the sexes over optimum sperm number and resulting spermatophore attachment duration. Premature removal of the ampulla may constitute a form of post-copulatory female discrimination (Sakaluk and Eggert, 1996), but it is unlikely that such a high number of matings observed here resulted in removal discrimination. Sperm loading, the adjustment of copulation duration and ejaculate size according to the risk of sperm competition (Parker *et al.*, 1990), has been observed in some other insects species (see for example Dickenson, 1986; Garcia-Gonzalez and Gomendio, 2004) including bush-crickets *Uromenus rugosicollis* (Vahed, 1997), and may well be a feature in some *Poecilimon*. Males may produce an optimum number of sperm ideal for sperm competition but in *P. laevisissimus*, females may “have the edge” over this conflict by being able to consistently consume and remove the nuptial gift and sperm ampulla before the sperm is fully transferred (reviewed in Vahed, 2007b; Gwynne, 2008). This assertion of a conflict between the sexes is further corroborated by evidence in *P. laevisissimus* where the pairs struggle for some time as the females appear to try and escape the clasp of the male’s cerci, and may additionally represent a form of female discrimination that leads to ‘fit’ males transferring more sperm overall (Eberhard, 1996).

In a different form, large quantities of sperm and spermatophore material are also wasted in *P. thessalicus*. We found that a large proportion of males did not transfer any sperm (18.5%; $n=27$). Spermatophores are expensive to produce (Dewsbury, 1982; Drummond, 1984; Simmons, 1990, 1995a; Heller and von Helversen, 1991; Vahed, 2007b; Lehmann, 2012), so those that fail to initiate represent a considerable waste in time and energy to *P. thessalicus* males. It may be that constriction of the females in scintillation tubes affected the onset of sperm transfer in *P. thessalicus*, although this is unlikely as onset was not affected in *P. laevisissimus*, *P. erimanthos* and a previously studied species, *P. hoelzeli* (R. Achmann *pers. comm.*). Importantly, total sperm numbers in ampullae that did not transfer were much less (by 63%) than the total number of sperm in ampulla that did transfer. While these data suggest that the mechanical initiation of sperm transfer may be dependent on the internal pressure or volume of sperm or ejaculate, mechanisms behind the sperm transfer process are poorly understood in bush-crickets. Future studies would benefit by further assessment of sperm transfer initiation during this critical onset period (Achmann *et al.*, 1992; Reinhold and Heller, 1993; Simmons and Achmann, 2000; Simmons, 2001).

Ultimately, no model we used for analysis could clarify the sperm transfer relationship between different species. Vahed (1994), however, previously fitted models using data from Gwynne *et al.* (1984) and Gwynne (1986) and showed that there was no difference between the sperm transfer curves for *Leptophyes punctatissima* and *Requena verticalis*, two species with varied sperm transfer profiles. Vahed (1994) suggested that the variation found within the sperm transfer among individuals of each species may be too large to easily detect a difference among species, although ultimately concluding that the function of the spermatophylax in *R. verticalis* is likely the same as that for *L. punctatissima*; to protect the ejaculate. As a comparison, we adopted the model used by Vahed (1994) and similarly found no difference

between the sperm transfer curves of the two most different *Poecilimon* species (i.e., *P. thessalicus* and *P. laevissimus*, $S=0.261$, $P=0.61$). We therefore suggest that the variation found within the sperm transfer among individuals of each species is too large to detect a difference between species and that the curves are unlikely to be considered the same.

It is important to keep in mind that the function of the nuptial gift is influenced by substances in the ampulla, other than sperm, that are transferred during mating (McCartney *et al.* 2008; McCartney, *et al.* 2010). Some of these substances are known to influence female intermating refractory period (Heller & Helversen, 1991; Heller & Reinhold, 1994; Lehmann and Lehmann, 2000b; Vahed, 2007b), the timing of oviposition (Arnqvist and Rowe, 2005; Vahed, 2007b), and the share of eggs that are laid with the donating male's nutritional investment (Simmons 1990; Vahed, 2003). Indeed, the positive relationship we found between spermatophore size and the proportion of sperm transferred may tie closely to the total volume of ejaculate substances transferred. If these substances affect fertilisation success or the incorporation of nutrients into offspring, the size or function of the nuptial gift may instead vary in accordance with these and be an important factor governing gift size (Vahed, 2003, 2007a; McCartney *et al.*, 2008).

It is unlikely that male *P. erimanthos* or *P. laevissimus* make significant paternal investments in their offspring in terms of nutrients. While paternal investment has been directly observed in *P. v. veluchianus* (Reinhold 1999), the disparity in time between complete sperm transfer and spermatophore consumption in *P. thessalicus* is also best explained by paternal investment. Larger spermatophores apparently increase male confidence in sperm transfer – and perhaps total ejaculate transfer – and are likely to ensure a greater level of paternal assurance. Furthermore, a recent study has shown that females of *Poecilimon* species that have males that invest more in spermatophore production will compete for access to males, invest relatively more in mating effort, and take greater risks in finding mates than species with smaller spermatophores (McCartney *et al.* 2012).

In terms of ejaculate protection and paternal investment, we present evidence that both sexual selection and natural selection influence spermatophore size within the single bush-cricket genus *Poecilimon*. However, irrespective of function, it is clear that sperm is wasted in all species presented here, and a better understanding is needed of the cost of sperm production as well as the mechanisms which affect sperm transfer if we are to fully understand the relationship between nuptial gift size, paternal investment, and ejaculate protection. Future studies would do well to assess how other substances in the ejaculate may control female re-mating, ova production and oviposition rate, and how the transference of these substances relate to gift consumption time.

ACKNOWLEDGMENTS

We thank K. Teltscher, L. Penny, M. Volleth and K. Witt for help in the field, K. Reinhardt, K. Reinhold and W. Edrich for discussion and, K. Vahed and M. Rossiter for helpful comments on earlier versions of the manuscript. Our research was supported by Massey University and D.F.G. (Deutsche Forschungsgemeinschaft) scholarships.

ABSTRACT

Mate choice copying was mostly described as a strategy employed by females to assess the quality of potential mates, but also males can copy other males' mate choice. In both cases, focal individuals show an increased propensity to copulate with a potential mating partner they could observe interact sexually with another individual (the 'model'). Sexual interactions, however, convey additional—partly conflicting—information to the choosing individual: females may try to avoid sexually active males due to a rougher courtship or coercive mating attempts, and males may respond to an increased sperm competition risk (SCR). How do females and males respond to different copying situations, in which the model individual either resides in the vicinity of a potential mating partner without physical contact (i.e., no harassment, and low SCR), or interacts sexually with the potential mating partner? Do individuals copy less in the latter situation? We investigated these questions in the guppy (*Poecilia reticulata*), a livebearing fish with internal fertilization, strong SCR among males, and frequent sexual harassment of females. Focal individuals could choose to associate with a large or a small stimulus fish, and mate choice tests were repeated after the previously non-preferred stimulus fish could be seen associating (low harassment and low SCR) or physically interacting (high harassment and high SCR) with a model individual. In a control treatment, no model was presented. We found both males and

* Corresponding Author's Email: cla.zim.uni@gmail.com (C.Z.).

females to copy similarly in both copying treatments, while no response was observed in the control. This contrasts with a study reporting that Atlantic molly (*P. mexicana*) males copy less under elevated SCR. Even though we lack a compelling explanation as to why both congeners might differ, we are tempted to argue that strong(er) benefits arising from copying may have selected guppies to copy in a broader range of contexts, including situations where the choosing individual incurs harassment or SCR.

Keywords non-independent mate choice, sexual selection, public information, social learning, sperm competition, mate choice copying

INTRODUCTION

Sexual selection, e.g., through mate choice, is a powerful evolutionary force, and individuals may integrate a wide range of information in their assessment of mate quality (Andersson 1994; Candolin 2003). Besides phenotypic traits like body coloration (Houde 1997; Price et al. 2008) and body size (Reznick and Endler 1982), dynamic traits like courtship displays (Darrow and Harris 2004; Rosenthal 2007) and parental care (Warner et al. 1995), also social interactions with conspecifics other than the choosing individual may serve as cues indicating mate quality (Ophir & Galef jr 2004; Ziege et al. 2012; Bierbach et al. 2013a). Especially in group-living animals that spend most of their lives surrounded by conspecifics, mating takes place not in privacy, but in a public domain (Valone and Templeton 2002; Danchin 2004; Dabelsteen 2005; Valone 2007; Druen and Dugatkin 2011). McGregor and Peake (2000), introduced the term ‘communication networks’ to account for the multi-directional nature of communicative interactions in animal societies. In such communication networks, by-standing individuals not involved in the sender-receiver dyad (but residing within a physical range allowing them to detect a signal), have the possibility to obtain information by observing communicatory interactions amongst other group members.

The process of extracting information from social interactions among other individuals within a communication network has been termed ‘social eavesdropping’ (Naguib et al. 2004; Dabelsteen 2005; Peake 2005; Valone 2007; Fitzsimmons et al. 2008). A widespread form of social eavesdropping in the context of mate choice involves the observation of aggressive male conflicts by females and subsequent choice of one of the rivals based on its performance (Ophir and Galef jr 2003; Aquiloni et al. 2008; Bierbach et al. 2013a). Another mechanism involves the observation of sexual interactions between males and females and subsequent choice of one of the involved individuals; termed ‘mate choice copying’ (Dugatkin 1992; Pruett-Jones 1992; Nordell and Valone 1998; Westneat et al. 2000; Bonnie and Earley 2007; Witte and Nöbel 2011).

Mate choice copying has been reported for various vertebrate taxa like birds (Höglund et al. 1990; Galef jr and White 1998; White and Galef jr 1999; Swaddle et al. 2005; Freed-Brown and White 2009) and mammals (Clutton-Brock and McComb 1993; Galef jr et al. 2008), including humans (Uller and Johansson 2003; Waynforth 2007; Yorzinski et al. 2010), but also in invertebrates (Mery et al. 2009; but see Auld et al. 2009). However, following Darwin’s groundbreaking work on sexual selection (Darwin 1871) most studies assumed females to be the choosing sex due to their higher investment in oocyte production compared to males (Andersson 1994). As a consequence, mate choice copying was most extensively studied in

females, especially in teleost fishes like guppies, *Poecilia reticulata* (Dugatkin 1992, 1996, 1998; Dugatkin and Godin 1992, 1993; Brooks 1999; Godin and Hair 2009), sailfin mollies, *Poecilia latipinna* (Schlupp et al. 1994; Witte and Ryan 1998, 2002; Witte and Noltemeier 2002; Witte and Ueding 2003), Hispaniola limia, *Limia perugiae* (Applebaum and Cruz 2000), Japanese medaka, *Oryzias latipes* (Grant and Green 1996) and Atlantic mollies, *Poecilia mexicana* (Heubel et al. 2008).

In theory, females can benefit from mate choice copying in at least two ways (after Gibson and Höglund 1992): (1) The accuracy of their own mate assessment may be increased, which provides a good opportunity for young females to copy decisions of older—more experienced—females (Dugatkin and Godin 1993). (2) Moreover, the time spent in assessing mate quality may be reduced (see Witte and Nöbel 2011 for discussion). The importance of female mate choice copying in shaping mating preferences can be illustrated in sailfin mollies (*P. latipinna*), in which genetically-based female preferences, such as the innate preference for large male body size, are reduced or even reversed through mate choice copying (Witte and Noltemeier 2002).

In promiscuous species, sexual activity (or the number of mating partners) may serve as an indicator of male quality. For example, females of the Atlantic molly were recently shown to have an increased propensity of interacting with males they saw mating with either a female or with another male, and the authors concluded that male sexual activity, whether in a heterosexual or homosexual context, is indeed a trait females find attractive (Bierbach et al. 2013b). However, poeciliid males exhibit high frequencies of sexual behaviors (Farr 1989; Magurran and Seghers 1994; Bisazza and Marin 1995; Houde 1997; Magurran 2001; Plath et al. 2003, 2007), while females can store sperm to fertilize a succession of broods and require only few copulations (Constantz 1984, 1989; Magurran and Seghers 1994; Pilastro et al. 2007). High frequencies of male sexual behavior are known to cause physical damage to the female genital tract (Magurran 2011), and females have less time available for feeding in presence of a harassing male as females spent considerable time trying to avoid sexual harassment (Magurran and Seghers 1994; Plath et al. 2007; Köhler et al. 2011). So, associating with a male that proofed its sexual activity (or at least its motivation to mate through its proximity to another female) obviously brings about an increased risk of sexual harassment. In the current study we asked whether females of two populations of guppies copy less under an increased level of sexual harassment (e.g., through observing sexual interactions between a male and a model female vs. mere associations between both).

For some species, also male mate choice copying has been described [sailfin mollies, *P. latipinna* (Schlupp and Ryan 1997; Witte and Ryan 2002), pipefish, *Syngnathus typhle* (Widemo 2005) and three-spined stickleback, *Gasterosteus aculeatus* (Frommen et al. 2009)]. However, male mate copying in internally fertilizing species—like mammals or poeciliid fishes—remains a conundrum as males incur an increased risk of sperm competition when choosing another male's previous mate (sensu Parker 1979; e.g., Constantz 1984; Becher and Magurran 2004). Nevertheless, poeciliid females are most receptive as virgins or for few days postpartum (Rosenthal 1952; Constantz 1984; Liley 1996) and, accordingly, only a small proportion of females in a population is receptive at the same time (Houde 1997; Magurran 2005). Furthermore, males evaluate female receptivity through so-called nipping behavior, where a male touches the female's genital opening with its snout (Parzefall 1969). Alternatively, males can observe sexual interactions of other males with females, and copying other males' mate choice may allow saving considerable energetic and opportunity costs

associated with mate searching and testing different females via nipping (sensu Schlupp and Ryan 1997). Additionally, in some poeciliids (including the guppy), last male sperm precedence is known (Farr 1989; Evans and Magurran 2001; Becher and Magurran 2004), which gives a competitive edge to the copying male even if the copied one has previously inseminated the female. Nevertheless, sperm competition plays a crucial role in poeciliid mating behavior (see also Evans and Magurran 2001; Dosen and Montgomerie 2004; Wong and McCarthy 2009; Evans and Pilastro 2011; Jeswiet et al. 2011), and a recent study by Bierbach et al. (2011a) found Atlantic molly (*P. mexicana*) males to copy less when sperm competition risk was high (e.g., when males observed sexual interactions between the model male and a stimulus female rather than mere associations without copulation).

While mate choice copying in general appears to be beneficial for both, males and females, risk of sexual harassment (for females) or risk of sperm competition (for males) ought to render certain copying situations less attractive. Specifically, we would expect a fine-tuning of mate choice copying behavior according to the nature of the observed interactions. In the current study, we compared male and female mate choice copying in guppies between two treatments (following the protocol of Bierbach et al. 2011a) during which focal individuals could either observe mere associations between a stimulus fish and a model (representing no sexual harassment or sperm competition) or direct sexual interactions (high risk of sexual harassment or sperm competition). Specifically, we asked (a) whether males and females show differences in their mate choice copying behavior and (b) whether the copying situation (no vs. high risk of sexual harassment or sperm competition) affects the strength of copying. In another experiment, we asked if males and females have a predilection for either of the two copying situations. We thus presented another set of males and females with video sequences showing a male or a female in association or engaging in sexual behavior and measured their preferences for both types of copying situations.

MATERIALS AND METHODS

Study Species and Animal Maintenance

Test fish came from two populations of guppies (*P. reticulata*): individuals from the first population were second to third generation descendants of wild-caught fish originating from Venezuela and were imported to Germany by ‘Aquarium Dietzenbach’ (coded as ‘wild-type’ in the following sections), while fish from the second population were regular aquarium fish (coded as ‘domestic’ in the later). Fish were reared in mixed-sex, single-population stock tanks (150–200 L) under a 12:12 light: dark cycle at a constant temperature of 28°C. All tanks were equipped with natural gravel and artificial plants to provide shelter. We fed the fish to satiation with commercially available flake food (TetraMin®) and food tablets (TetraTabs®) twice daily, and frozen chironomid larvae and *Artemia salina* nauplii once a week.

Experiment 1

To compare male and female mate choice copying in different copying situations (see Introduction), we largely followed the experimental protocol of Schlupp and Ryan (1997) that was recently modified and used to investigate male mate choice copying under sperm competition risk in the Atlantic molly (*P. mexicana*, Bierbach et al. 2011a). All focal fish were isolated prior to the tests in groups of < 20 individuals in 100-L aquaria for at least 24 hours. Focal and stimulus individuals stemmed from different isolation groups to prevent effects of familiarity (Bierbach et al. 2011b). A standard test tank (80 cm length × 30 cm height × 30 cm depth) was divided into five sections of equal size: The two lateral compartments were divided by transparent Plexiglas partitions and contained the stimulus fish (Fig. 1). The remaining compartment was visually divided in two lateral preference zones and a central neutral zone by marks drawn on the front of the tank. The tank was filled to a height of 15 cm with aged tap water of 27–29°C and was aerated and heated whenever no experiment was conducted.

As both sexes of the guppy are known to have an intrinsic mating preference for large body size (Reynolds and Gross 1992; Herdman et al. 2004), we took two different-sized stimulus individuals from one isolation tank and introduced them into one of the two lateral compartments each. Stimulus individuals were exchanged between subsequent trials. Afterward, a focal fish of the opposite sex was introduced into a clear Plexiglas cylinder (10 cm diameter), placed centrally in the neutral zone, and was left undisturbed for 5 min. After this habituation period, we gently lifted the cylinder and measured the amount of time the focal fish spent in each of the two preference zones, i.e., near the large and small stimulus fish during a 5-min observation period. To account for potential side biases, the focal fish was then gently placed back into the cylinder and stimulus fish were interchanged. After 5 min of habituation, measurement was repeated for another 5 min. Like in previous studies, we decided *a priori* to discard trials in which focal fish spent more than 80% of their choice time during both parts of the experiment in the same compartment as side biases (e.g., Plath et al. 2004), but no cases of side-bias were observed. This initial preference test consisting of two measurements is henceforth called the first part of a trial (Figure 1a).

Times spent near each stimulus fish during the two test units were summed, and if the focal fish spent more than 66% of the time with one of the stimuli they were considered to have shown a preference and were used for the subsequent test phases. Trials in which focal fish did not show a strong preference were terminated at this point (Schlupp and Ryan 1997). Out of 81 initially tested wild-type males, 15 did not show a preference for one of the two stimulus females; similarly, 17 out of 85 females showed no preference. In the domestic stock, 17 out of 61 initially tested males did not show a preference and out of 58 females, 16 tests were terminated after the first part of a trial.

Directly after the first part, the focal fish was retransferred into the Plexiglas cylinder in the center of the neutral zone (“observation phase”; Figure 1b). We created situations during which the focal fish either had no opportunity to copy (control), or it could observe visual interactions and associations between the model individual and the formerly non-preferred mate, or physical (i.e., sexual) interactions of the latter two. To do so, focal fish were randomly assigned to one of the following three treatments: In the control treatment (1), an empty transparent Plexiglas cylinder was placed in the front portion of the non-preferred individual’s compartment. To control for any changes in the behavior of the stimulus fish due to this procedure, we introduced another Plexiglas cylinder also into the compartment of the formerly

preferred individual but covered this portion of the stimulus compartment by an opaque Plexiglas sheet and thus prevented the focal fish from seeing it (Figure 1b).

Figure 1. Experimental setup used to examine mate choice copying in *P. reticulata*. In the first preference test (a), we measured the time the focal individual spent in the preference zones (pz1 or pz2) near either stimulus fish (sz1 or sz2). During the observation phase (b), focal fish were randomly assigned to one of three treatments: treatment 1, control without a model individual; treatment 2: visual association, where the focal fish could observe a model individual visually interacting with the formerly non-preferred stimulus, and treatment 3: sexual interactions, during which they could observe physical interactions between the model individual and the formerly non-preferred stimulus. The second preference test (c) was analogous to the first and enabled us to compare preferences before and after the focal fish had the possibility to copy the model's mate choice. Depicted is the test scheme for male mate choice copying; tests for female mate choice copying were conducted analogously.

Treatment (2) was similar to previous mate copying tests in *P. latipinna* (Schlupp and Ryan 1997). Again, two Plexiglas cylinders were placed in the front portion of both compartments holding the stimulus fish (see above), but we now introduced one model individual per cylinder, so the focal fish could observe a model of the same sex visually interact with the formerly non-preferred mate, but was prevented from seeing the other model interact with the formerly preferred mate.

To allow physical interactions between the model individual and the formerly non-preferred stimulus, we introduced the model individual without a Plexiglas cylinder into the

partition of the formerly non-preferred mate [treatment (3)]. Hence, the model individual could interact sexually with the stimulus fish. The previously preferred mate was able to interact visually with a fish of the opposite sex in a Plexiglas cylinder just like in treatment (2) (the cylinder with this fish was again hidden behind an opaque plastic sheet as described before). We quantified pre-copulatory behavior (nipping, mean $\pm$ SE, wild-type 10 ± 8 ; domestic 8 ± 10) and copulations (gonopodial thrusting, wild-type 3 ± 5 ; domestic 1 ± 3) in the stimulus-model pair during the 20 min of observation. After the 20-min observation phase, the model individuals were removed and measurement of association preferences (including switching of side assignments of the stimulus fish between the two test units) was carried out as described for the first part of the experiment (Figure 1c). After the tests, the standard lengths of all fish were measured to the nearest millimeter (Table 1a).

Table 1. Body size of the test fish. Given are mean ($\pm$ SE) standard lengths (SL in mm) of the focal, stimulus (large and small) as well as model fish ('preferred' = model interacted with preferred stimulus; 'non-preferred' = model interacted with non-preferred stimulus)

Population/Sex	focal	large	small	model preferred	model non-preferred
a) Experiment 1					
Domestic, females ($N = 42$)	33.0 ± 0.7	27.5 ± 0.3	21.5 ± 0.2	33.6 ± 1.0	34.4 ± 0.7
Domestic, males ($N = 44$)	22.7 ± 0.4	35.5 ± 0.5	23.8 ± 0.4	23.3 ± 0.4	22.9 ± 0.4
Wild-type, females ($N = 68$)	28.9 ± 1.1	24.8 ± 0.6	18.2 ± 0.4	27.3 ± 1.3	28.3 ± 1.3
Wild-type, males ($N = 66$)	23.7 ± 0.3	36.4 ± 0.4	29.4 ± 0.6	24.3 ± 0.5	24.6 ± 0.6
b) Experiment 2					
Wild-type, females ($N = 21$)	28.0 ± 2.8				
Wild-type, males ($N = 22$)	21.0 ± 1.5				

Experiment 2

To test if males and females have a predilection for either of the two copying situations, we used dichotomous association preference tests in conjunction with video playback techniques (Makowicz et al. 2010; Bierbach et al. 2013b). We created video sequences showing (1) a male and a female separated by an (invisible) PVC partition or (2) a pair of fish allowed to interact freely. We used only wild-type fish in this experiment. Males for the production of video recordings were isolated for one week in 10-L tanks to ensure that they were motivated to mate. The recording tank was divided into two same-sized compartments by an opaque PVC partition and a camcorder (Panasonic HDC-TM60EG-K) was set up 9 cm from the front wall to capture both compartments simultaneously. For the videos showing 'visual association', one female (SL $\pm$ SD, 29.2 ± 0.9 mm) and one male (22.6 ± 0.7 mm) were placed in either compartment, and after a 5-min acclimatization phase were filmed for at least 6 minutes. For videos showing direct interactions, we removed the PVC-partition after the acclimatization phase so males could mate with the female. We recorded numbers of nipping (8 ± 8) and mating

attempts (8 ± 5). For each treatment and prepared 10 videos (resolution 800 x 600 px, saved as avi-files) that were later displayed via MS Powerpoint (Microsoft Office 2010).

For the binary association preference tests we followed the protocol of Bierbach et al. (2011a). The test tank (60 x 30 x 30 cm) was visually divided into three sections: two lateral preference zones of 10 cm width and a central, neutral zone of 40 cm width. The tank was filled with aged tap water to a height of 25 cm. Water was heated and aerated between trials, but heater and air stone were removed prior to testing. The bottom of the test tank was covered with fine white quartz sand. Illumination was provided by two 60 W fluorescent lamps on the ceiling of the test room. We placed two identical video screens (Samsung SyncMaster P2470LHD, 24 in.; resolution 1,280 × 768 pixels) at both short sides of the test tank and covered all remaining parts of the test tank's walls (including the front wall) with grey cardboard to reduce disturbances from the outside. The test fish was observed from above by use of a mirror.

To initiate a trial, we introduced a focus fish into a transparent Plexiglas cylinder placed centrally in the neutral zone and gave the test subject 5 min for acclimatization, during which the monitors showed a uniformly gray display. Afterwards, we released the focal fish and started the video playback, showing the two types of video sequences (see above) on the left and right side (side-assignment was altered between trials). We measured the time the focal individual spent in each preference zone for 5 min. Focal fish were then reintroduced into the Plexiglas cylinder and given another 5 min of habituation while both screens displayed gray background only. Subsequently, measurement of association times was repeated for another 5 min with sides of the video presentation interchanged. We summed up association times from both parts and calculated the strength of preference (SOP) as follows:

$$SOP = \frac{t_{sex\ int} - t_{vis\ assoc}}{t_{sex\ int} + t_{vis\ assoc}},$$

where $t_{sex\ int}$ is the time spent in the compartment next to the sexual interaction-sequence and $t_{vis\ assoc}$ the time spent next to the visual association-sequence. Upon completion of a trial, we measured SL of the focal fish to the nearest millimeter (Table 1b).

Statistical Analysis

All data were tested for normal distribution using Kolmogorov-Smirnov tests and were presented as mean $\pm$ standard error (SE) throughout. Statistical analyses were conducted using IBM SPSS 18.

Experiment 1

In a first step, we evaluated the focal individuals' preference for large body size. We compared the amount of time focal fish spent near large and small stimulus individuals during the initial preference test (first part) and during the second part of the tests for all three treatments separately, using paired sample *t*-tests.

Our main question was whether focal fish would alter their individual mate choice decisions after they had observed a model individual visually [treatment (2)] or sexually [treatment (3)] interact with the formerly non-preferred stimulus. We, therefore, calculated a score expressing the change of mating preference as the difference between individuals'

relative association time with the initially non-preferred female during the second part and relative association time near the same female during the first part ('copying score'; see Heubel et al. 2008; Bierbach et al. 2011a, 2013b), such that no change would lead to a score of zero, and positive values would indicate a relative increase in time spent near the initially non-preferred stimulus due to copying. Scores were compared using a full-factorial univariate General Linear Model (GLM) with 'treatment', 'sex' and 'population' as fixed factors. As mate choice copying in other poeciliids depends on the size difference between the two stimulus individuals (Witte and Ryan 1998), we initially included stimulus body size difference (SL large – SL small) and focal individuals' body size as covariates but removed them as neither the covariates themselves nor any of their interactions had a significant effect (body size difference: $F_{1, 198} = 2.11$, $P = 0.15$; focal body size: $F_{1, 198} = 0.22$, $P = 0.64$). We also removed the non-significant 3-way interaction of all main factors from the final model ($F_{2, 208} = 2.55$, $P = 0.081$) as well as non-significant 2-way interactions (treatment $\times$ sex: $F_{2, 209} = 2.1$, $P = 0.16$; sex $\times$ population: $F_{1, 210} = 0.59$, $P = 0.44$). We used Fisher's LSD tests to *post hoc* analyze differences between treatments.

Figure 2. Time focal fish spent in association with the large and the small stimulus individuals during the first part of the choice tests (left) and during the second part in the three copying treatments. During the observation phase preceding the second part of the choice tests either no copying was possible (control), or a model fish could interact visually or physically with the previously non-preferred stimulus. Depicted are association times ($\pm$ SE); significant P -values are from paired t -tests (* $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$).

To test for a potential effect of body size differences between model and focal individuals on the strength of mate choice copying (copying score), we included body size difference (SL focal – SL model) as a covariate in another GLM while analyzing only the subset of data from treatments (2) and (3).

To evaluate whether the number of sexual interactions that a focal fish observed during the observation phase affected the strength of copying in treatment 3, we included numbers of nippings and mating attempts as covariates in another GLM analyzing the subset of data from treatment (3).

Experiment 2

We compared times males and females spent near the video sequences showing sexual interactions and visual associations for each sex separately using paired *t*-tests. Furthermore, we compared the strength of preference (SOP) between males and females in a GLM including ‘video ID’ as random factor and focal individuals’ body size (SL) as a covariate.

RESULTS

Experiment 1: Mate Choice Copying in Males and Females

Preference for Large Mating Partners

Males and females of both populations spent significantly more time in association with larger stimulus fish during the first part of the preference tests (Fig. 2). This preference was largely maintained during the second part of the tests (i.e., after the observation phase) with two notable exceptions: females of both populations ceased expressing a preference for the larger stimulus male in treatment (2) (visual association) and spent almost equal amounts of time near the two stimuli. Also, no significant preference was seen in males from the domestic stock in treatment (3) (sexual interaction), but qualitatively males still tended to spent more time associating with the larger female ($P = 0.11$; Fig. 2).

Changes in Individual Preferences

The final GLM detected a significant effect of the main factor ‘treatment’ and *post hoc* LSD tests indicate that, overall, test subjects showed consistent mate choice in the control treatment (copying scores close to zero in Fig. 3; LSD: $P < 0.001$ compared to both other treatments), but copied to a similar extent in treatment (2) (positive copying score for ‘visual association’) and treatment (3) [positive copying score for ‘sexual interaction’; LSD test, treatment (2) vs. treatment (3): $P = 0.52$]. Moreover, a significant interaction effect of ‘treatment by population’ was uncovered, suggesting that the two populations differed in their responses to the different copying treatments, even though effect size (estimated as partial η^2) was lower for the interaction term compared to the main effect ‘treatment’ (Table 2). Nevertheless, estimated marginal means derived from GLM revealed that domesticated guppies, overall, copied more than wild-type guppies (Fig. 3). Sexes did not differ statistically in their copying behavior (Table 2).

We also tested for an effect of the focal and model individuals’ body size difference on the strength of copying within the subset of data from treatments (2) and (3). However, body size difference had no statistically significant effect (GLM; $F_{1, 142} = 0.40$, $P = 0.53$). In another GLM, we could not detect an effect of the amount of sexual behavior shown by the stimulus-model pair in treatment (3) and strength of copying (nipping behavior: $F_{1, 64} = 0.85$, $P = 0.36$; copulations: $F_{1, 64} = 0.18$, $P = 0.68$; courtship displays: $F_{1, 64} = 0.27$, $P = 0.60$).

Table 2. Results from a univariate GLM with ‘copying score’ as the dependent variable and ‘treatment’ (control, visual association and sexual interaction), ‘sex’, ‘population’ (domestic or wild-type) and their two-way interaction terms as fixed factors. Significant effects are in bold face

Source	Mean Square	<i>df</i>	<i>F</i>	<i>P</i>	Partial η^2
Treatment	1.67	2	19.63	<0.001	0.17
Sex	0.17	1	2.17	0.16	<0.01
Population	0.04	1	0.29	0.64	<0.01
Treatment * Population	0.41	2	4.56	0.01	0.05
Error	0.09	213			

Figure 3. Changes in individual mating preferences when focal fish were given an opportunity to copy another individual's mate choice. During the observation phase preceding the second part of the choice tests either no copying was possible (control, left) or a model fish could interact visually (middle) or physically (right) with the previously non-preferred stimulus fish. Depicted are copying scores (see main text), whereby positive values indicate that preferences for the initially non-preferred stimulus individuals increased in strength.

Experiment 2: Preference for Different Copying Situations

Neither females nor males showed a preference for either type of video (males, visual association: 194.7 ± 17.3 s; sexual interactions: 172.6 ± 16.6 s; paired *t*-test: $t_{21} = -0.91$, $P = 0.37$; females, visual association: 205.5 ± 20.6 s; sexual interactions 161.6 ± 22.6 s; $t_{20} = -1.16$, $P = 0.26$). Also, there was no significant effect of the factor ‘sex’ ($F_{1,30} = 0.14$, $P = 0.71$) when comparing SOP-values using GLM. Likewise, the covariate (focal individuals’ body size) had no significant effect ($F_{1,30} = 0.20$, $P = 0.66$).

DISCUSSION

Copying the mate choice decisions of other individuals provides benefits to both males and females, as copying helps reduce costs of mate searching (Gibson and Höglund 1992; Schlupp and Ryan 1997; Witte and Noltemeier 2002). At the same time, mate choice copying is

associated with costs, namely increased sperm competition risk for males that copy other males' mate choice (see Evans and Magurran 1999) and increased sexual harassment for copying females (see Plath et al. 2007). Cost-benefit trade-offs are predicted to shape mate choice decisions in general (Kokko et al. 2003), and similar trade-offs ought to affect copying behavior as well.

Guppies have a promiscuous mating system characterized by strong mating competition among males, leading to high levels of sperm competition and sexual harassment (Magurran and Seghers 1994; Evans and Magurran 1999; Plath et al. 2007), and so the costs associated with mate choice copying should be high. Our current study was motivated by the hypothesis that individuals copy opportunistically when costs associated with mate choice copying are moderate or low (i.e., in the visual association treatment), but cease copying other individuals' mate choice decisions when costs are high (in the direct interaction treatment). Support for this hypothesis comes from a study that found males of the Atlantic molly (*P. mexicana*), another member of the family Poeciliidae, to reduce mate choice copying when sperm competition risk was experimentally increased using the same experimental approach we employed here (Bierbach et al. 2011a).

Our study revealed that male and female guppies copy the mate choice decisions of conspecifics, and there was no significant difference between sexes in strength of mate choice copying. Contrary to prediction, however, we found no significant difference between the copying situation involving mere associations between stimulus and model individuals [treatment (2)] as compared to the situation involving sexual interactions [treatment (3)]. We do not have a compelling explanation at hand for the apparent differences between Atlantic mollies (Bierbach et al. 2011a) and guppies (this study). It seems tempting to argue though that copying provides greater benefits to the copier in guppies than Atlantic mollies, such that male and female guppies are willing to accept costs arising from sperm competition and harassment and thus, copy in a broader range of social contexts. Future studies should make an attempt to shed light on this question. For example, video animation techniques could be employed to create virtual copying situations that gradually increase the amount of sexual interactions between stimulus and model individuals. Comparing Atlantic mollies and guppies in such an experimental design would be an elegant test to our new hypothesis, as Atlantic mollies are predicted to cease copying at a lower threshold value of sexual behavior. This experiment, of course, still leaves open the important question of *why* species of poeciliids might differ in their propensity to copy the mate choice of others. Comparative approaches using different species and genera of poeciliid fishes might shed light on the question of how differences in social organization, mate encounter rate, male aggression, and other factors, affect the evolution of copying behavior.

Beside the strong treatment effect, we also found a weak but statistically significant interaction effect of 'population by treatment', indicating differences in the magnitude of mate copying between populations, and domestic guppies copied more than the descendants of wild-caught animals. Noteworthy, several studies reported on a lack of female mate choice copying behavior in feral and wild-type pet shop guppies (Brooks 1996, 1999; Lafleur et al. 1997), resulting in some controversy about the importance of mate choice copying for sexual selection (Dugatkin 1998). The majority of studies suggest that female mate choice copying is a universal and widespread behavior—at least in guppies (Dugatkin 1992, 1996; Dugatkin and Godin 1992, 1993; Godin & Hair 2009)—while Brooks (1998) argued that population differences may exist. Our results indeed suggest some variation in mate choice copying among populations. We have

no compelling explanation at hand as to the question of why domestic guppies copied more than wild type guppies. The exact founder population(s) from which the artificial strain was derived is unknown, so it remains possible that the ancestors of our domestic strain already exhibited stronger copying; likewise, we cannot rule out the possibility that the domestication process has selected for increased copying, even though the latter scenario seems unlikely.

ACKNOWLEDGMENTS

We like to thank Holger Geupel for help with animal care. Financial support came from the German Research Foundation (Deutsche Forschungsgemeinschaft, DFG) to MP (PL 470/3-1).

Chapter 37

SEXUAL SELECTION UNDER PARENTAL CHOICE: MATING STRATEGIES AND REPRODUCTIVE SUCCESS

Menelaos Apostolou and Marianna Zacharia

University of Nicosia, Nicosia, Cyprus

ABSTRACT

Across pre-industrial human societies mating is regulated, with arranged marriage, in which male parents select spouses for their female relatives, being the primary mode of long-term mating. This chapter reviews the model of sexual selection under parental choice that offers a good account for these patterns of human mating. This model postulates that parent-offspring conflict over mating induces parents to control the mate choices of their children, and the spouses they select for them are individuals who conform best to their preferences. By doing so, parents become a significant evolutionary force affecting the course of sexual selection. The model is applied in order to achieve a comprehension of the evolution of specific mating strategies. In particular, it is argued that in a context where mate choice is regulated, at least three mating strategies can thrive: addressing parental choice, addressing female choice and circumventing parental and female choice by force.

INTRODUCTION

When Darwin introduced his theory of sexual selection, which postulates that certain traits have evolved to permit individuals to attract and retain mates, he identified female choice to be a primary sexual selection force (Darwin, 1871). In particular, he argued that since it is men who strive to gain access to women and not the other way round, traits which make a man to be more attractive to women are selected and increase in frequency in the population.

Darwin did not provide an explanation of why it is typically men who struggle to gain access to women and not the opposite. This theoretical gap that was successfully addressed and closed a hundred years later by Robert Trivers. Trivers (1972) emphasized that women devote, supply and provide more to their offspring than men which makes them the scarce reproductive resource over which men strive to gain access. Trivers' argument contributed considerably to

the theory of sexual selection under female choice, as it offered more solid foundations. The aforementioned, combined with the observation that in Western societies men seem to sacrifice substantial resources to gain access to women, initiated and enhanced intense theorizing and empirical work centered on the model of sexual selection under female choice.

For example, Zahavi (1975) suggested that costly traits, such as the peacock's tail, evolved to reliably communicate male fitness to females. This theory was utilized by Zahavi & Zahavi (1997) and Miller (2000) who articulated that men have evolved a tendency to engage in costly behaviors like in sports in order to communicate their abilities to women in a cheat-proof fashion. Likewise, since sexual selection is directed by female choice, female preferences direct its course. Accordingly, Buss (2003) and other researchers examined mate preferences, with a focus on female mate preferences.

The model of female choice, although it bears some good theoretical basis and appears to apply to a Western context, it has a fundamental weakness namely, it is not consistent with the patterns of human mating found in modern and historical pre-industrial societies. In these societies, women are not free to exercise choice, as their mating decisions are regulated by their parents, typically their fathers, who select spouses for them (Apostolou, 2010b; Blood, 1972). Since the way of life over the previous two million years of human evolution more closely bears a resemblance to the way of life of modern pre-industrial societies compared to that of Western societies, it is reasonably possible that these patterns of mating portrayed mate choice during most of human evolution (Apostolou, 2010b). This delineates that the model of sexual selection under female choice is insufficient in explaining how sexual selection works in our species.

A different model has been recently put forward which better fits the mating patterns observed in pre-industrial human societies (Apostolou, 2007b, 2010b). In this model, conflicting interests over mating induce parents to regulate mate choice and choose individuals who comply best with their preferences, as spouses for their children. The purpose of this chapter is to review this model and apply it in understanding the evolution and the prevalence of male mating strategies. The fundamental constituent of the model is parent-offspring conflict over mating, which will be discussed next.

PARENT-OFFSPRING CONFLICT OVER MATING

All children's genes come from their parents, yet not all of parents' genes are inside their children. Consequently, as parents and children are not genetically identical, the traits of a mating candidate which are most beneficial and desirable to children are not essentially so for their parents. For this reason, parents and children have evolved asymmetrical preferences over traits, which offer them asymmetrical benefits (Apostolou, 2007a; 2008; Buunk, Park, & Dubbs, 2008; Trivers, 1974).

Perhaps the most characteristic case is genetic quality. The coefficient of relatedness of parents to children is 0.5, but the coefficient of relatedness of grandparents to grandchildren is half as much that is, 0.25. Consequently, the probability of a particular gene of an individual being passed into the next generation by a spouse or in-law would be 50% or 25%, respectively. This means that parents obtain less genetic benefits from a prospective mate of high genetic quality than their offspring (Apostolou, 2007a; Buunk et al., 2008). Beauty is a proxy of genetic

quality (Thornhill & Gangestad, 1993), and therefore, is preferred more in a spouse than in an in-law (Apostolou, 2008; Buunk et al., 2008). Preference divergence is not limited solely to beauty, as research has demonstrated that parents and offspring have diverse preferences concerning family and religion background, and exciting personality (Apostolou, 2008; Buunk et al., 2008; Perilloux, Fleischman, & Buss, 2011).

Asymmetrical preferences lead to conflict among parents and children as a result of the trade-off nature of mating: constrained by their own mate value, parents and offspring have to make compromises with respect to a mating candidate's desirable qualities. However, since the two parties do not share identical preferences, they are going to make dissimilar compromises (Apostolou, 2008; Buunk et al., 2008). Therefore, if children solely exercise mate choice, they will compromise more than their parents would like over certain traits, like industriousness and social status, in order to get an attractive spouse. Conversely, genetic quality associated with beauty is less important to parents, thus the advantage from this trait is insufficient to compensate for the loss of other desirable traits. For that reason, the children's mate choice imposes a cost upon parents in the form of loss in desirable traits (Apostolou, 2008).

A study examining the tradeoffs of in-law and mate choice, asked parents to design an ideal spouse for their children, and their children to design an ideal spouse for themselves (Apostolou, 2011). Participants were given a budget of mate points and they were asked to allocate them across several desirable traits. The study demonstrated that children assigned fewer points in traits, such as similarity in religion and good family background in order to get more of exciting personality and beauty. Their parents, on the other hand, assigned fewer points on exciting personality and beauty in order to get more of good family background and similarity in religion.

These findings indicate that if children are left on their own to exercise mate choice, this choice will impose a cost on their parents with regard to loss in desirable traits. This stimulates and encourages parents to control their children's mate choices, which in turn has an impact on the course of sexual selection.

THE MODEL OF PARENTAL CHOICE

Parent-offspring conflict over mating mandates that mate choice left in the hands of offspring does not maximize the fitness of parents. As a consequence, substantial evolutionary pressure is exercised on the parents to regulate the mating decisions of their children.

The prolonged period during which children rely on parental investment for survival and reproduction and the fact that parents and their kin are physically stronger than their children permit parents to control mate choice (Apostolou, 2007b). By doing so, they become effectively a sexual selection force, as traits that make an individual more likely to be chosen as an in-law are selected and increase in frequency in the population compared to less desirable ones.

Since females invest more in their offspring, they become the scarce reproductive resource to which males are seeking access (Trivers, 1972). Thus, by controlling this "resource", parents effectively control mating (Apostolou, 2007b). Furthermore, lenient parental control over female children possibly bears detrimental consequences, such as unwanted pregnancy (Perilloux, Fleischman, & Buss, 2008). Consequently, parental control is biased against female offspring, something that is also facilitated by the fact that daughters are physically weaker than

sons. Parental choice is also asymmetrical in favor of male parents. By means of greater physical strength, exclusive use of weaponry and control of political institutions, male parents have more influence over their offspring's mate choices than female parents (Apostolou, 2007b).

Nevertheless, parental control over mating is not absolute. Parents cannot always effectively "protect" their children, and their control diminishes as they become older and physically weaker and their offspring stronger and less dependent on parental investment (Apostolou, 2007b). Lastly, control over mating produces evolutionary pressures on children to evolve adaptations, such as psychological manipulation of their parents to accomplish their goals concerning mate choice (Trivers, 1974).

SEXUAL SELECTION UNDER PARENTAL CHOICE IN HUMAN SOCIETIES

Sexual Selection under Parental Choice in Pre-Industrial Societies

In pre-industrial societies offspring depend on their parents and close kin for food, support and protection. Accordingly, we expect that parents in these societies dominate mate choice. Apostolou (2007b), in an attempt to examine whether this is the case, he coded the mating patterns of a sample of 190 foraging societies spread across the globe. In these societies, parents exercise considerable control over the mating behaviour of their offspring, as the most common type of marriage is arranged marriage, since in 70% of the societies in the sample marriages were arranged. Marriage as the result of free courtship is found only in a small number of cases (4.3%). In arranged marriage, men, usually fathers, regulate the selection process, but it is not rare for women to be also influential. Finally, there is still the possibility for offspring to exercise choice by escaping, divorcing or forming extramarital affairs.

Moreover, Apostolou (2010b) analysed data from the Standard Cross Cultural Sample and found that in agropastoral societies the most frequent marriage type is arranged marriage, and marriage arrangements are controlled by males. Additionally, in agropastoral societies women are more likely, compared to men, to have an arranged marriage and to be married at a younger age. Nevertheless, children can still exercise choice by employing various means, such as divorce and extramarital affairs. Moreover, comparisons between agropastoral and foraging societies revealed that parents exercise more control over the mating decisions of their children in the former than in the latter societies. Male parents are also more frequently reported to dominate marriage arrangements in agropastoral societies than in hunting and gathering ones.

These patterns of mating have significant evolutionary implications. More specifically, the separation between agropastoral and foraging pre-industrial societies resembles the two most important stages of human evolution: humans lived as hunters and gatherers for the most part of human evolution, than over the last 10,000 years, there was a shift to a mode of subsistence based on agriculture and animal husbandry (Lee & DeVore, 1968). Therefore, by studying modern pre-industrial societies, we can make valid inferences concerning mating patterns in ancestral human societies (Ember, 1978; Lee & DeVore, 1968). Thus, as parental choice is dominant in modern foraging societies, we can infer that it was also dominant in ancestral

foraging ones (Apostolou, 2007b). This is supported by research based on phylogenetic analysis which endeavors to recreate the conditions of ancestral societies (Walker et al., 2011).

Moreover, it can be further inferred that the agricultural revolution at the onset of the Holocene (10,000 years ago) gave rise to a subsequent increase in the influence of parents, and especially male parents, over the mating choices of their children (Apostolou, 2010b). As a matter of fact, we do not need to make assumptions for pre-modern agropastoral societies, as data for the mating patterns in these societies is already available from historical sources. This evidence indicates that parents, primarily male ones, had been arranging the marriages of their offspring, and in particular of their daughters, in ancient Greece (Vrissimtzis, 1997), ancient Rome (Balsdon, 1962), Imperial China (Gernet, 1970) and in pre-Victorian England (Stone, 1990).

Sexual Selection under Parental Choice in Post-Industrial Societies

In contrast to pre-industrial societies, the extensive educational needs of technology-based societies require marriage to be delayed, in anticipation of the conclusion of one's training. For that reason, individuals are married later in life, at a period when they are relatively independent from their families. Moreover, social protection systems, such as the welfare state, police, human rights etc., alleviate individuals' dependence on their family. Similarly, the legal system prevents the use of physical force, so parents are restrained from freely imposing their will by means of physical punishment. Since parents cannot use their children's reliance on their investment and their physical strength as means of coercion, they cannot directly dominate their mating choices. Consequently, individuals in post-industrial societies have the benefit of autonomy and lack of restrictions concerning mate choice.

However, parental behaviour has been formed by evolution in order to attempt to dominate the mating behaviour of children, which denotes that even if parents cannot do so directly, they will attempt to do so by employing indirect means. To begin with, parents regulate considerable resources, for which their children are not unconcerned thus, these can be used to affect mate choice. For instance, manipulation of inheritance rights can give parents, particularly rich ones, a lever for effective manipulation (Apostolou, in press). Moreover, parents also employ means, like 'cajolery, persuasion, appeals to loyalty, and threats' (Apostolou, in press; Sussman, 1953) to influence the mating behaviour of their offspring.

In the same vein, contemporary Chinese parents cannot inflict their choices on their children, but they still persist to exercise the function of the facilitator through their own social systems (Ikels, 1985). Chinese parents in the USA attempt to create situation in which their children can get together with other Chinese children of a desirable background. For example, they may stage a barbecue when an eligible relative from out of state comes to visit (Ikels, 1985). Although the real potency of parental choice in post-industrial societies remains to be estimated, the evidence currently existing indicates that parents are influential over mating choices.

IN-LAW PREFERENCES

Marriage adds a new member to the family unit, who contributes significantly to its survival and reproductive efforts. In-laws integrate into their new family, supporting its subsistence activities (hunting, gathering, animal herding etc.), offering political support through their family relations, physical support in case of external threats (raids, wars, feuds etc.), their genes, and so on. However, in-laws differ. For example, some are diligent while others are indolent; some enjoy vigorous health while others suffer from chronic illness; some come from wealthy and powerful families while others have humble origins. Consequently, since prospective in-laws vary in their qualities, they also vary in the advantages they can offer to parents.

This reveals that parents have been experiencing strong evolutionary pressures to evolve preferences that permit them to select those in-laws who are most valuable to them (Apostolou, 2007a, 2010a). In contrast, parents who do not share such preferences are just as likely to choose a hard-working in-law as a lazy one. Therefore, the former gain a selective advantage over the latter, successfully augmenting the frequency of the genes that confer the disposition for these preferences in the population (Apostolou, 2007a). The result of this process is that parents have been equipped with well-defined in-law preferences.

Given that not all the traits in an in-law provide parents with the same benefits, parents are likely to have stronger preferences for qualities which are more beneficial for them. Moreover, parental preferences are expected to be dependent upon the sex of the in-law. Specifically, the division of labour assigns or attributes diverse tasks and roles to men and women in a given society. For instance, in all recorded human cultures, men dominate over women in controlling resources (Whyte, 1978). In modern Western post-industrial societies, the wealthiest self-made individuals are men, while the wealthiest women are in the 'Rich List' because they inherited, or married into wealth. Accordingly, parents should value traits related to the capacity to acquire resources more in a son-in-law than in a daughter-in-law.

Two studies have been conducted to date which endeavour specifically to identify parental preferences. To begin with, Apostolou (2007a) requested from a group of British parents to rate the desirability of several traits in a prospective son-in-law and daughter-in-law. Parents appeared to have a hierarchy of preferences in which specific traits were deemed to be more essential than others. In particular, traits such as kind and understanding, good health, and good earning capacity were located at the top of the parental hierarchy, followed by traits such as education/intelligence, good cook/housekeeper, and good family background located in the middle of the parental hierarchy. Traits such as physically attractive and chastity were located at the bottom of the parental preference hierarchy.

Moreover, parents rated traits in a different way in a daughter-in-law and a son-in-law. In particular, qualities such as ambition/industriousness, good financial prospects, and wealth were preferred more in a son-in-law than in a daughter-in-law, while traits, such as good housekeeper and good looks were preferred more in a daughter-in-law than in a son-in-law. Finally, both mothers and fathers were found to have the same opinion in terms of what they seek in an in-law of either sex.

The second study, using anthropological evidence from 67 pre-industrial societies, identified 13 desirable qualities that parents seek in an in-law (Apostolou, 2010a). Among the most frequently reported traits were good character, good family background, industry and

good worker, and subsequently favourable social status, wealth, and similar family social status. The least commonly reported traits were good looks and chastity. It was also found that traits such as good economic prospects, wealth and favourable social status were regarded highly more in a son-in-law than a daughter-in-law, while chastity was regarded highly more in a daughter-in-law than a son-in-law.

Although not purposely intended to pinpoint in-law preferences, other studies provide information on the traits parents desire in an in-law. More specifically, Hynie et al. (2006) investigated in-law preferences of Chinese immigrants in North America and results reveal that good social status and understanding are among the most preferred traits. Borgerhoff Mulder (1988) reported that, among the pastoral Kipsigies in Kenya, parents prefer as sons-in-law individuals who enjoy high social status, are wealthy, educated, have a good character and are diligent. Yu, Proulx, and Shepard (2007) found that Matsigenka women in Peru prefer men with masculine faces as sons-in-law and interpreted this finding as a preference for good providers, as masculine men are, on average, perceived as better resource providers. Finally, Apostolou (2007b) found that among foragers, parents seek sons-in-law who are good hunters and have a good family background, while they prefer daughters-in-law who are industrious and come from good families.

The knowledge of parental preferences, and how these deviate from the preferences of their children, can provide us with an understanding of the prevalence of certain mating strategies in the population.

MALE MATING STRATEGIES

Polymorphism in Mate Choice

Men seek to gain reproductive access to women, but the gatekeepers to this access are other men (usually fathers) who search for sons-in-law with particular traits. This creates substantial evolutionary pressures for men to attract interest as in-laws from parents and particularly from male parents. Nevertheless, women's mate choices are not entirely restricted by their parents, since they can engage in informal relationships before marriage and in extramarital relationships subsequent to marriage, while they can also divorce the spouses their parents have chosen for them (Apostolou, 2010b). Consequently, there is freedom for women to exercise choice, which delineates that there have also been evolutionary pressures on men to discover wide-ranging ways to appeal to women as mates.

To put it differently, there have been at least two mating niches that men can address: The parental niche (being selected through parental choice) and the female niche (being selected through female choice). The evolutionary effect of the existence of two niches is that men may have evolved to attend to both parental choice and female choice, or some men may have evolved to attend to parental choice and others to attend to female choice.

The latter scenario is more likely because, in cases where a species occupies multiple niches, a polymorphic equilibrium (e.g., two or more distinct specializations) is usually more optimal than a monomorphic one (e.g., a single specialization), as specialists are more efficient than generalists (Wilson, 1994). This is due to the fact that a male specializing in appealing to parental choice obtains reproductive advantages from marriage without having to bear the cost

of appealing to female choice. A male specializing in appealing to female choice may obtain reproductive advantages by engaging in different casual relationships without bearing the costs of appealing to parental choice.

As a species we are a polymorphic: Some individuals have blond hair, while others have dark hair; some individuals have blue eyes and others have green eyes. We are also polymorphic in terms of behavior. Some individuals are hard-working and others are lazy; some are kind and others are evil and so on. Approximately half of the variations between people with respect to personality are due to the fact that they share diverse genes (Plomin et al., 2008). Accordingly, polymorphism, being frequent in our species, should also exist in mating behavior, mainly in light of the fact that there is more than one mating niche.

Our knowledge of in-law and female preferences permits us to hypothesize how the two male morphs are likely to be structured. To begin with, men specializing in attracting interest from parents are likely to give emphasis to their personality and family background, and pay less attention to their physical appearance. They are also likely to be concerned about impressing and gaining the respect of other men. Conversely, men specializing in attracting the interest of women are likely to accentuate more their physical appearance, being charming, but pay less attention in communicating their good family background.

Assuming that parental choice has been dominant throughout human evolution, we would expect that the male morph that addresses parents should have been much more frequent than the male morph that addresses women. To put it in a different way, the parental niche has been much bigger than the female niche, leading to an equilibrium where the majority of men specialize in attracting interest from parents, and a minority in attracting interest from women.

Overall, men are likely to have evolved two strategies in order to obtain access to the opposite sex, one through females themselves and one through their parents. It is also of paramount importance to stress that there is a third approach, which permits men to force mating access to women.

THE EVOLUTION OF RAPE

Circumventing Parental Choice

When they look for sons-in-law, parents are in search for men who are endowed with qualities which are advantageous for them. Evidence from modern and historical societies reveals that parents are interested in finding sons-in-law who have a high resource-generating capacity, have a good family background, control wealth, and have a good character (Apostolou, 2010a, 2012; Borgerhoff Mulder, 1988; Koster, 2011). Men who lack desirable qualities, such as social status and find themselves in a context where mating is regulated, endure a substantial reproductive loss, since they are inclined to be excluded from mating or have to compromise by settling for a woman of low mate value.

To be more precise, parents with daughters of elevated mate value (e.g., attractive, young, etc.) are not going to be willing to give them as wives to men of an inferior mate value (e.g., men who lack desirable traits). Therefore, if a man of inferior mate value seeks to gain parental approval, he needs to address parents whose daughters also have an inferior mate value (e.g., are older, unattractive, have children from previous marriages, etc.), and who are thus less

reluctant to accept him as a son-in-law. In fact, this man will endure substantial fitness losses, as he will have to either settle for a woman of low mate value or opt out from the reproductive process.

In addition to parental choice, there are two related factors which also operate to alleviate the ability of men, who have a low mate value, to attract desirable wives. One is polygyny, which is practiced in most of the pre-industrial societies and acts to exclude low status men from gaining reproductive access (Blood, 1972). The reason is that high mate value men are able to attract multiple wives, leaving those at the bottom of the hierarchy single. In the same vein, hypergyny, that is, women marrying up the social hierarchy, a common practice in many societies, pulls women out of the lower classes, leaving a lot of low-status men without wives (Boone, 1986).

In this context, then, a forced-sex mating strategy can decrease the reproductive costs that a man would probably suffer by circumventing parental choice, permitting sexual access to women of high mate value, women that these low mate value men could not have accessed in any other way. This predicts that rapists are mostly young men of low mate value. This prediction is consistent to the findings of several studies (Thornhill & Palmer, 2000; Thornhill & Thornhill, 1983). This predicts also that the victims of rape should predominantly be high mate value women, who would not be accessible by these rapists in any other way. Consistent with this prediction, the majority of rape victims are frequently young women at the peak of their fertility (Greenfield, 1997; Kilpatrick et al., 1992; Thornhill & Palmer, 2000).

Circumventing Female Choice

In societies where mating is controlled, women still have some space to exercise mate choice. For instance, they can exercise mate choice by forming extramarital relationships or taking a divorce and getting married later, when their parents are no longer alive (Apostolou, 2010b). Consequently, a man can address female choice directly. However, women are in search of men with desirable traits, such as high resource acquisition capacity and physical attractiveness (Buss, 2003). This indicates that a man who lacks these traits is unlikely to be able to successfully appeal to female choice if he addresses high mate value women. He will be more effective, however, if he addresses low mate value women, such as older ones who are less likely to receive offers from men of high mate value. Nevertheless, getting married to an older woman will not enhance his fitness much, as the reproductive years of that woman have already been or will soon be exhausted.

A man will inevitably need to address female choice within marriage. In particular, a man's mate value may decrease if for instance he suffers an injury from a fight, or experiences a status loss. This will make his wife perceive him as a less desirable mate. Additionally, in a context where mating choice is regulated, a man may effectively pass through parental choice, but this does not mean that he will instantly obtain sexual access to his wife, as the latter may decline her husband's requests to permit him to gain sexual access.

Consequently, a forced-sex mating strategy can offer fitness benefits by permitting men to circumvent female choice. The female choice within marriage cases predicts further that rape would also occur within marriage. Consistently with this prediction, between 10% and 26% of women report experiencing marital rape (Russell, 1990; Watts, Keogh, Ndlovu, & Kwaramba, 1998). It is further predicted that rape will be more likely to occur when the mate value of the

husband diminishes (e.g., he loses his job) or the mate value of the wife augments (e.g., she loses weight).

Finally, in societies which practice arranged marriage, rape within marriage enhances the strength of parental choice as a sexual selection force because it makes the choices of parents on their daughters consequential. This predicts that in these societies, the parents of a man may prompt him to force sex on his wife if she rejects his requests to obtain sexual access, and the parents of the bride may also encourage or at least accept such action. This prediction also remains to be addressed by future research.

In a pre-industrial context, a forced-sex mating strategy can endow substantial reproductive advantages to inferior mate value men by enabling them to circumvent parental and female choice. This strategy is not of course cost-free, otherwise nearly all men would adopt it most of the times. In particular, a rapist is likely to meet the fierce reaction of a woman's parents and other kin, he is likely to meet the resistance of the woman, which might result in physical injury, and he is likely to face the vengeance of the woman, particularly in the case of marital rape.

CONCLUSION

The model of parental choice predicts that for the greatest part of the period of human evolution, parental choice constituted a significant sexual selection force, with individual mate choice still likely to be exercised. This prediction is consistent with evidence from the anthropological and historical records which demonstrate that across human pre-industrial societies mate choice is regulated, but there is also room for individuals to exercise their own choice.

Based on the abovementioned, it has been argued that men have evolved at least three diverse strategies in order to obtain sexual access to the opposite sex: they can address female choice, parental choice, or attempt to circumvent both selection mechanisms by force i.e., through rape. Future research needs to explore each strategy and assess their relevant fitness payoffs.

Chapter 38

MELON GERMPLASM CHARACTERISTICS, DIVERSITY, PRESERVATION AND USES

C. Mallor and A. Díaz*

Unidad de Hortofruticultura, Instituto Agroalimentario de Aragón (IA2)
(CITA-Universidad de Zaragoza), Zaragoza, Spain

ABSTRACT

The need for germplasm banks that safeguard the melon genetic resources is more than justified by the genetic erosion aggravated in the last few decades, not only in the cultivated materials, but also in traditional landraces and wild relatives. The classical and new technologies employed in all stages, from the sample prospecting to resources management, with the conservation and evaluation of the plant resources in between, are described. An added value to these germplasm collections is the use of the genetic resources there preserved in the melon breeding programs. The access to wild genetic resources make possible to exploit them, for instance, for germplasm enhancement incorporating disease resistances in elite varieties. In this sense, conventional breeding methods have rendered unquestionable benefits to agriculture, which can be accelerated by the appearance of new biotechnological tools and genomic resources as a result of the increasing number of vegetable species whose genomes have been or are being sequenced. All germplasm banks, and those preserving vegetable resources like melon in particular, will have to face up to the challenge of characterizing genetically their collections in order to maximize their use in breeding strategies assisted by molecular tools, like molecular markers. At the same time, the use of molecular markers can help to efficiently manage the resources by the creation of core collections. This would alleviate the problems derived from the high number of entries in many of them that is compromising some of the purposes for which they have been created, the conservation and the use of the genetic diversity originally prospected. The advantages in terms of labor and economical investment of preserving, characterizing and using a reduced subset of samples without a considerable sacrifice of the genetic diversity, are undeniable.

1. GENERAL INTRODUCTION: THE NEED FOR GERMPLASM BANKS

The need for germplasm banks that safeguard the vegetable genetic resources is more than justified by the genetic erosion aggravated in the last few decades, not only in the cultivars, but also in traditional landraces and wild relatives. The case of melon (*Cucumis melo* L.) serves as an example of this dwindling in variety. At the beginning of the twentieth century, the commercial seed houses in USA offered more than 300 melon varieties and only eight decades later, less than 30 of them could be found in the National Center for Genetic Resources Preservation (NCGRP, USA). On top of this preservation of the plant genetic biodiversity, germplasm banks can also be considered as a gene reservoir to breed crops.

Until 2009, there were 21,268 germplasm banks included in the World Information and Early Warning System (WIEWS) on Plant Genetic Resources for Food and Agriculture (PGRFA) spread all around the world (FAO, 2016), though not uniformly, as for instance in the African continent, there are many countries without any germplasm bank (Figure 1).

Figure 1. Distribution of all the germplasm banks around the world (A); and only those with more than 10,000 accessions (B) surveyed until 2009 (Source: Wiews, 2009. FAO).

There are some supranational organizations aimed at improving the accessibility to the information gathered by these germplasm banks on their respective collections. At a global level, Genesys is a portal that not only offers characterization and evaluation information about PGRFA from germplasm banks around the world, but it also supplies the seeds (Genesys, 2015). Genesys manages information of 8,679 accessions of *C. melo* coming from germplasm banks of 24 countries, mainly the United States (4,184 accessions), Spain (1612) and Russia (931) (Figure 2A). At the European level, the European Cooperative Programme for Plant Genetic Resources (ECPGR) maintains a catalogue of 4,274 accessions belonging to the *C. melo* species in the database named EURISCO (Eurisco, 2016), in which their passport data can be consulted. Twenty-one countries contribute to it with passport data of melon accessions, Spain being the one with the most significant participation (Figure 2B).

In many countries, the collections are centralized in national inventories. In the case of melon, the national collections keeping the highest number of accessions are those from Spain (1,555), Russia (931), United States (500), Germany (443), and Ukraine (406). The Spanish national inventory is managed by the National Plant Genetic Center (CRF). Among its tasks, the CRF keeps a replicate of the accessions maintained in the participant institutions (Table 1) and develops, publishes and keeps updated the inventory of the collections. In many of these banks, a great effort has been made to rescue landraces that would otherwise have disappeared by now, frequently being collected from local farmers, though the collections include all sort of accessions, from wild melon relatives to breeding lines (Figure 3).

2. COLLECTION, CONSERVATION, CHARACTERIZATION AND EVALUATION OF MELON RESOURCES

A number of expeditions to collect *C. melo* accessions in an attempt to preserve the maximum variability within the species have been set on around the world in the last decades. A record of many of these prospecting works carried out between 1974 and 2012 is available at the Biodiversity International webpage (Biodiversity International, 2016; Figure 4). A total of 836 samples belonging to 664 different accessions of *C. melo* (apart from many other wild relatives within the genus *Cucumis*), collected in 42 expeditions in 30 countries, were prospected. More than the 20% of these samples were surveyed in Spain.

Melon plants produce fruits containing a type of seed called orthodox (Roberts, 1973), that is, they undergo maturation drying. This facilitates enormously their *ex situ* conservation, as they can tolerate extensive desiccation and also chilling, being stored dry at low temperatures (around -20°C) for long periods of time, maintaining an acceptable viability. This conventional storage method is easy to perform and affordable, what makes unnecessary to implement more sophisticated methods, like *in vitro* slow growth tissue culture or cryopreservation, though they can be used in melon with other purposes, as it is the case of the *in vitro* procedures.

The characterization and evaluation of melon accessions for agronomic and morphological traits promote their utilization in breeding programs. Many germplasm banks are making an immense effort to carry out the characterization of the material that is multiplied routinely. This work makes possible the identification of accessions with desirable characteristics and, hence, very interesting from a breeding point of view, but it also contributes to the proper management of the banks, for instance, allowing the identification and discard of duplicates.

As it happens in many other species, *C. melo* is integrated by a wide and very dissimilar array of forms. Firstly, it is divided into two subspecies, *melo* and *agrestis* (Jeffrey, 1980). Several horticultural groups compose each of them. Their number vary depending on the author consulted, though one of the latest and more accepted classifications (Pitrat, 2008) divides the subspecies *melo* into ten groups (*cantalupensis*, *reticulatus*, *adana*, *chandalak*, *ameri*, *inodorus*, *chate*, *flexuosus*, *dudaim*, and *tibish*) and the subsp. *agrestis* into five (*momordica*, *conomon*, *chinensis*, *makuwa*, and *acidulus*). Foreseeably, these groups will suffer modifications, as some of them are heterogeneous and the inclusion of some accessions in them is difficult.

Figure 4. Geographical location of the 836 *Cucumis melo* samples prospected between 1974 and 2012 in collecting missions supported by Biodiversity International (Source: Biodiversity International, 2012).

The availability of a guideline for cucurbit descriptors (Esquinas-Alcazar and Gulik, 1983) allowed unifying criteria for the morphological characters of interest in melon. More recently, the UPOV descriptor list for melon, which includes up to 76 characters (UPOV, 2014), has aided in selecting the traits to evaluate (Szamosi et al., 2010). In this sense, the International Plant Genetic Resources Institute (IPGRI) has published a list of minimum highly discriminating descriptors for melon (Table 2) that become easier to handle along with the maintenance of the collections (IPGRI, 2003).

Table 2. List of a minimum number of descriptors that allows an unambiguous discrimination of melon accessions

Part of the plant	Character	Categories
Whole plant	Seedling vigor	Poor; intermediate; vigorous
	Plant growth habit	Compact; dwarf; determinate; indeterminate; multilateral; other
Branch	Internode length	Very short; short; short-intermediate; intermediate; long
	Number of plant branches	
Leaf	Leaf shape	Entire; trilobate; pentalobate; 3-palmately lobed; 5-palmately lobed; other
	Leaf lobes	Shallow; intermediate; deep
	Central leaf lobe shape	Broadly ovate; shallowly oblong; narrowly oblong; elliptic; other
	Leaf color	Light green; green; dark green; variable; other
	Leaf petiole hairiness	Sparsely hispid; hispid; hispidulous; retrorse strigose; lanate; other
	Leaf persistence	Low; moderate; high
	Leaf senescence	Slight visual senescence; moderate senescence; conspicuous concurrent senescence
Inflorescence	Sex type	Monocious; andromonoecious; gynoeious female; male sterile; female sterile; other
	Days to 50% flowering	
	Flower color	White-yellow; yellow-cream; yellow; dark-yellow; orange; green; other
	Ovary pubescence length	Short; intermediate; long
	Ovary pubescence type	Spreading hairs; appressed hairs
Fruit	Fruit shape	Globular; flattened; oblate; elliptical; pyriform; ovate; acorn; elongate; scallop
	Fruit length/width ratio	
	Time of maturity	Early (<70 days); intermediate (70-90 days); late (91-110 days); very late (>110 days)
	Predominant fruit skin color	White; light-yellow; cream; pale green; green; dark green; blackish-green; orange; brown; grey; other
	Secondary fruit skin color	White; light-yellow; cream; pale green; green; dark green; blackish-green; orange; brown; grey; other
	Secondary skin color pattern	No color; speckled (spots <0.5 cm); spotted, blotchy (spots >0.5 cm); striped; short streaked; long streaked; other
	Fruit surface	Smooth; grainy; finely wrinkled; deeply wrinkled; shallowly wavy; rare warts; numerous warts; lightly corked/netted; heavily corked/netted; sutures; other
	Bitterness of mature fruit	Low; intermediate; high
Seed	Seed size	Very small; small; intermediate; large; very large
	Seed shape	Roundish; elliptical; oval; triangular; pine seed type; other
	100-seed weight	

Source: IPGRI, 2003.

With an efficient handling of the characterization and evaluation data, donor genotypes with outstanding characteristic for important traits can be identified. Furthermore, the transfer of both qualitative and quantitative traits from wild into domesticated forms has also become an attractive objective in breeding programs.

3. MELON GENETIC RESOURCES MANAGEMENT

As in any other crop, a deep knowledge of the genetic variation and structure of melon is a prerequisite for the conservation and exploitation of the biodiversity existing within the species. In this sense, the melon research community has been making use of the molecular markers available in each moment. All the markers listed below have played an important role in the identification and evaluation of the variability present in the species.

3.1. Morphological Markers

Before the development and routine use of molecular markers, a great number of morphological traits were used to identify and classify the variability present in melon. In this sense, characters related to the vegetative and flowering state of the plant, as well as to the fruit, were scored. Categories based on qualitative characters of the fruit, like aroma, taste and pulp or skin color, can also be established.

The first taxonomic classification of the species in “botanical groups” or “horticultural varieties” are based in these types of data, as those reported by Naudin (1859). One of the latest intraspecific classifications based on morphological traits is the one proposed by Pitrat (2008), who defined 15 botanical groups, belonging to two subspecies, *agrestis* and *melo*, as commented above. This subdivision has recently been confirmed with the use of molecular markers (Serres-Giardi and Dogimont, 2012; Esteras et al., 2013) though there are some discrepancies in the groups comprised in each subspecies (Serres-Giardi and Dogimont, 2012), what reveals the need of using easy to evaluate markers in taxonomic studies.

The evaluation of morphological traits has been frequently combined with agronomical (Escribano and Lazaro, 2009; Roy et al., 2012), physiological (Soltani et al., 2010) and biochemical data, like pH, total soluble solids (TSS) and the content of several polysaccharides (sucrose, glucose and fructose), organic acids (ascorbic acid) and vitamins (carotenoids) in the melon pulp (Stepansky et al., 1999; Dhillon et al., 2007; Fergany et al., 2011; Roy et al., 2012), among others. It is also common to complete the research on melon diversity using morphological traits with the study of agronomical characteristics, like yield-related parameters, and pest and disease resistance (Staub et al., 2004; Dhillon et al., 2007; Fergany et al., 2011; Roy et al., 2012). However, the use of morphological traits as markers is hindered by numerous factors, such as the influence of cultural management and environmental conditions on the phenotype. Furthermore, sometimes they reveal themselves insufficient to discriminate among different melon accessions and to assign them to the varietal groups described (Trimech et al., 2013). This is why morphological traits may only provide partial taxonomic information. To overcome this limitation, scientists have resorted to molecular markers to strengthen their results from morphological data in classification and diversity studies (Stepansky et al., 1999;

Luan et al., 2008; Sensoy et al., 2007; Phan et al., 2010; Parvathaneni et al., 2011; Sestili et al., 2011; Yildiz et al., 2014) and, the other way round, phenotypic characters has complemented molecular data, for instance, in the construction of genetic maps (Oliver et al., 2001; Perin et al., 2002; Cuevas et al., 2008), as it will be tackled in more detail in the following sections.

3.2. Biochemical Markers: Isozymes

Isozymes have been the biochemical markers most widely used in plant breeding. They represent the different biochemical forms of an enzyme codified by different alleles of the same gene (Soltis and Soltis, 1989).

The easy, quick and affordable methodology needed to employ these codominant markers favored their use in melon in areas like molecular breeding, to identify progenies in an early growth stage, what is applicable to seed purity tests (Issiki et al., 1991; Kato et al., 1998); in systematic, to determine the genetic distance with wild and cultivated relatives (Chen et al., 1997) and among melon accessions with different geographical origin (Akashi et al., 2002; McCreight et al., 2004); and in genetic mapping (Staub et al., 1998).

Isozymes have some disadvantages because they are gene products, so their expression is affected by the environment, sometimes it is tissue-specific and can be subjected to selective processes. For these reasons, scientists working on melon have been combining the use of isozymes with DNA-based markers, for instance, to explore the intraspecific variation of the species (Staub et al., 1997), or to construct a linkage map (Oliver et al., 2001).

3.3. Genetic Markers

Genetic markers offer information directly about the genotype, quite the opposite than the previous ones, which were based on the phenotypes and the gene products, respectively. This is the reason why they are presently the most extensively used markers. Among them, amenable to automation markers seem to be the most suitable ones for the management of genetic resources.

Virtually all sorts of DNA markers have been employed in melon and, in many cases, to explore, characterize and manage the diversity of the species. The markers most commonly used for this purpose have been: RFLPs (Restriction Fragment Length Polymorphisms, Botstein et al., 1980) and AFLPs (Amplified Fragment Length Polymorphisms, Vos et al., 1995), which detect the polymorphism created in the DNA by the alteration of the target site of a restriction enzyme either by punctual mutations or deletions and insertions; RAPDs (Random Amplified Polymorphic DNAs), which make use of arbitrary, short primers to amplify genomic DNA, what renders a band profile considered as a dominant marker (Welsh and McClelland, 1990; Williams et al., 1990); SCARs (Sequence Characterized Amplified Regions, Paran and Michelmore, 1993), which can be obtained from the markers mentioned above by cloning and sequencing one of the fragments obtained previously and designing specific primers to amplify the region by PCR, getting in most cases a more specific and robust dominant marker; microsatellites or SSRs (Simple Sequence Repeats, Hamada et al., 1982), which are multi-allelic, hypervariable, and codominant markers based on short tandemly repeated DNA motifs; and SNPs (Single Nucleotide Polymorphisms, Cooper et al., 1985), which consist of single

DNA base differences between homologous genomes. Other types of markers, like ISSRs (Inter-Simple Sequence Repeats, Zietkiewicz et al., 1994), derived from SSRs, that amplifies inter-microsatellite sequences, or SRAPs (Sequence-Related Amplified Polymorphism, Li and Quiros, 2001), consisting of the amplification of open reading frames (ORFs), have had a minority use in melon though have also thrown useful information on the genetic diversity of the species (Parvathaneni et al., 2011; Sestili et al., 2011; Yildiz et al., 2011).

RAPDs, being one of the first genetic markers to be available, were commonly used alone (Mliki et al., 2001) and together with morphological traits (López-Sesé et al., 2003; Luan et al., 2008; Yi et al., 2009) to explore melon germplasm diversity and to assist in curation tasks. RFLPs have been used, together with RAPDs (Silberstein et al., 1999), or RAPDs and AFLPs (Garcia-Mas et al., 2000), to dissect the molecular variation in different accessions within the species. Similarly, the use of different types of markers, like RAPDs and SSRs, has aided in the estimation of the genetic variation of melon germplasm to design strategies for large collection evaluation (López-Sesé et al., 2002). Among the studies on melon diversity using molecular markers recently published, SSRs (Akashi et al., 2001; Chiba et al., 2003; Monforte et al., 2003; Escribano et al., 2012; Guo et al., 2012; Kacar et al., 2012; Serres-Giardi et al., 2012; Hu et al., 2014; Ning et al., 2014; Raghami et al., 2014; Hu et al., 2015) or any of their variations, like EST-SSRs (Kong et al., 2011), are those more commonly chosen, what is a consequence of their great polymorphism and amenability to automation by PCR. In the case of SNPs, the melon genome (Garcia-Mas et al., 2012) and its transcriptome (Blanca et al., 2012) sequencing have contributed hugely to the availability of this kind of marker to the scientific community, turning them into good genome coverage supplier markers. In fact, SNPs have been recently used to dissect the variability present in a broad array of melon accessions, like commercial cultivars, breeding lines, landraces, feral types, and wild relatives, for trait as important from an economical perspective as the sugar accumulation and the climacteric behavior (Leida et al., 2015). SSR and SNP analyses have revealed themselves very useful to compare the genetic variability present in modern melon cultivars and landraces to an ancient extinct landrace (Szabo et al., 2005), making possible to trace the closest relative in the present melon germplasm to that medieval accession. Chloroplastic markers (one SSR and one SNP) have also been used to typify Chinese Hami melons by maternal lineages in comparison with occidental cultivars within group *inodorus* and germplasm coming from other countries in Central and South Asia (Aierken et al., 2011). The genetic relationship elucidated with genetic markers (Tanaka et al., 2007), together with the population structure of the different groups (Esteras et al., 2013), open up new opportunities for a more rational use of the melon germplasm richness in breeding programs.

Table 3. Databases containing information of molecular markers developed in melon

Database name	Website
CmMDb: <i>Cucumis melo</i> Microsatellites Database	http://65.181.125.102/cmmdb2/index.html
Cucurbit Genomics Database	http://www.icugi.org
Melonomics	https://melonomics.net/
VegMarks: a DNA marker database for vegetables	http://vegmarks.nivot.affrc.go.jp

The creation of databases with information about molecular markers developed in melon and other vegetables belonging or not to the Cucurbitaceae family (Table 3) facilitates access to information continuously being expanded.

As commented above, molecular markers, in general, have come to complement data from phenotypic features and, in most cases, both results support each other. Literature is riddled with examples of this synergic relationship between phenotypic and molecular data in studies about melon germplasm diversity as cited above, becoming patently clear however that molecular markers are more reliable and accurate identifying genetic diversity (Parvathaneni et al., 2011). The construction of a molecular database of the collections would assist managing them, for instance making decisions about new prospectings, based on the genetic diversity already collected, or determining if the new acquisitions are redundant.

3.4. Core Collections

Paradoxically, the intense work carried out prospecting, collecting and preserving plant genetic resources has resulted in many germplasm banks collapsing. The use of molecular markers can help to efficiently manage the resources by the creation of core collections. This would alleviate the problems derived from the high number of entries in many of them that is compromising some of the purposes for which they have been created, the conservation and the use of the genetic diversity originally prospected. The advantages in terms of labor and economical investment of preserving, characterizing and using a reduced subset of samples without a considerable sacrifice of the genetic diversity, are undeniable. Genetic markers have revealed themselves as the most appropriate tool for this task and, among them, SSRs seem to be the most useful thanks to their multiallelic nature and the easy methodology required. In melon, two core collections have been built up to now, making use of SSR markers (Hu et al., 2015), or AFLP markers for the actual selection of the core set and SSRs for a subsequent validation (Frary et al., 2013). In both cases, the accessions come mainly from Asia, what has been recently postulated as a center of origin of melon cultivation (Sebastian et al., 2010), which are conserved in the National Mid-term Genebank of Watermelon and Melon (Zhengzhou, China) (Hu et al., 2015), and the National Seed Genebank at the Aegean Agricultural Research Institute (AARI, Menemen, Izmir, Turkey). The core collections represented the 10% (Frary et al., 2013), and 19% (Hu et al., 2015) of the whole set of accessions, both being comprised in the range (5-20%) of most core collections of seed-propagated crops (van Hintum et al., 2000). Regarding the genetic variability present in the core collection respect to the source one, 87% and 100% of the SSR alleles were retained, respectively. Undoubtedly, these core sets will make easier the management of those particular collections and the access of breeders to the desirable alleles contained in them.

There is no panacea for many of the challenges that curators need to face. Even if classic and new techniques can complement each other, certain tools are more appropriate than others for some specific applications, like the examples exposed above in which genetic markers (AFLPs and SSRs) have been used to create core collections. Similarly, the perfect molecular marker does not exist, at least, for the moment. They all have advantages and disadvantages, either of technical, methodological, economic or even of analytical nature. Depending on the particular objective to be addressed, different types of markers can be the most suitable ones.

At the time of choosing the marker to be used, several factors need to be weighed, such as the degree of polymorphism required, and the time, labor and economical cost.

4. USES OF MELON GERMPLASM

Exotic and commercial melon germplasm has been extensively used in phenotypic screenings, for instance, to find resistance to diseases (Thomas and Jourdain, 1992; Boiteux et al., 1995; Pan and More, 1996; Wolff and Miller, 1998; Wolukau et al., 2007) and plagues (Garzo et al., 2004), but also tolerance to abiotic stresses, like dehydration (Pandey et al., 2011; reviewed in Kumar et al., 2012; Mundalia et al., 2015). To exploit all the possibilities that the rich melon germplasm offers to the breeding programs, especially the exotic accessions, it is necessary to characterize it and genotype it with molecular markers. Many scientists have started to make an effort in this sense, including accessions within the subspecies *agrestis* in their diversity studies, as it has been mentioned above (Esteras et al., 2013; Hu et al., 2014; Koffi et al., 2014). Molecular markers developed in melon have also been used extensively in genetic breeding programs to aid in the selection of individuals with desirable characteristics (Marker Assisted Selection, MAS) in an early stage (Kim et al., 2010; reviewed in Oumouloud et al., 2013; Díaz et al., 2014; Perpiñá et al., 2016). For this, obtaining linkage maps in melon and, even more, merging them into consensus ones (Díaz et al., 2011 and references in it contained; Díaz et al., 2015), has been determinant to identify markers linked to the traits of interest. Genetically distant melon sources, for instance, belonging to the two *C. melo* subspecies, *melo* and *agrestis*, have been commonly crossed to obtain breeding and/or mapping populations (Fita et al., 2006; reviewed in Díaz et al., 2011; Yuste-Lisbona et al., 2011; Hwang et al., 2014). Among the traits analyzed in those studies, there are not only resistances to diseases, but also other economically important ones, like those related to the quality (i.e., sugar and organic acid content), size and morphology of the fruits, or plant growing habits, directed to obtain dwarf plants.

A way of exploiting the variability present in the melon germplasm is by the construction of exotic libraries introgressing genomic regions from the wild and exotic accessions (i.e., from the subspecies *agrestis*) onto the background of elite cultivars. Obviously, for these tools to become useful, a genetic map, especially of the introgressed region, is required. The availability of markers amenable to genotype by high-throughput technologies, like SNPs, has sped-up the process, as in the case of the IL (Introgression Line) collection recently obtained in the cultivar Charentais background (Perpiñá et al., 2016). The exotic accession used in this case was PI 161375, named Songwan Charmi, which belongs to the subspecies *agrestis*, and bears many interesting characteristics from a breeding point of view, like resistance to several pests and diseases. The results reported there are very promising as pre-breeding lines for traits with a high economic impact, like high sugar content or delayed climacteric ripening, are being generated.

On the other hand, the use of wild or non-cultivated germplasm in breeding has some clear disadvantages, like the transference of undesirable characteristics to the elite cultivar background by linkage drag, making necessary several generations of backcrossing and selection to get rid of them completely. Again, the combined use of state-of-the-art and classical technologies has assisted scientists to overcome this obstacle. Recently, Sherman et

al., (2013) have employed microarrays together with bulk segregation analysis to finely map the region responsible for the acidity in the melon pulp (*pH* locus). Obviously, this is an irrelevant aspect in sweet melons, in which the pH is very high (around 6.0), though the consumption of many other types of melons is restricted to when they are still young due to the high accumulation of organic acids at ripe stage caused by their allelic composition at *pH* locus. The SNPs linked to the *pH* locus obtained by these authors will make possible to obtain melons with new taste combinations in a more directed way and, hence, investing less time and effort.

5. CHALLENGES AND PROSPECTS

The drastic price reduction in genotyping and next-generation sequencing technologies make feasible the genetic characterization of germplasm collections. In fact, the whole soybean collection (18,480 accessions) maintained at the United States Department of Agriculture (USDA), has already been genotyped with 52,041 SNPs (Song et al., 2013). These data, together with those coming from historical phenotypic characterization, has been exploited to develop prediction models for traits as important from an economic point of view, as protein and oil content, or yield (Jarquin et al., 2016). This approach undoubtedly raises the value of the samples and their data treasured at the germplasm banks. In this case, the collection consisted of domesticated accessions. It would be of great interest to include in these genotyping platforms wild crop relatives as the wild germplasm represents a valuable source of variability with a huge potential in breeding programs. In melon, some of the most important germplasm banks have already tackled this endeavor (Esteras et al., 2013), as it is the case of the Institute for Conservation and Improvement of Valentian Agrodiversity (COMAV, Valencia, Spain).

All germplasm banks, not only those preserving vegetable resources and melon, in particular, will have to face up to the challenge of characterizing genetically their collections in order to maximize their use in breeding strategies assisted by molecular tools, like genetic markers.

ABSTRACT

The evolution of cultivated plants played important role in the ascent of humanity. A large number of theories exist about the evolution of the European grapevine (*Vitis vinifera* ssp. *sativa* L.), it is supposed, that woodland grape itself, or crossing with other species could be the progenitor. The woodland grape (*Vitis vinifera* ssp. *sylvestris* GMEL.) in Hungary is a protected species. The quest and preservation of its populations are significant in terms of nature conservation and reserve of biodiversity as well.

In the years of 2010-2015 32 woodland grape genotypes were collected in the Szigetköz, Hungary and ex-situ preserved in the genebank National Agricultural Research and Innovation Centre, Research Institute for Viticulture and Enology, in Badacsonytomaj, Hungary. In 2015-2016 these genotypes were characterised by SSR analysis and were compared with 20 grape rootstocks and 16 *Vitis vinifera* ssp. *sativa* cultivars to ensure the true-to-typeness.

Based on the results dendrogram was constructed. In the dendrogram the *Vitis vinifera* ssp. *sylvestris* accessions form a distinct group, but are closer to the *Vitis vinifera* ssp. *sativa* cultivars, than to the rootstocks. This raises the probability, that these accessions are true-to-type woodland grapes.

INTRODUCTION

The evolution of cultivated plants played important role in the ascent of humanity. Research of their origin and evolution started at the beginning of the 20th century, but till nowadays a lot of questions remain open.

A large number of theories exist about the evolution of the European grapevine (*Vitis vinifera* ssp. *sativa*). According to De Candolle (1894) the grapes originate from the Trans-Caucasus. Based on the geographical principle in evolution by Darwin (1883) the regions of the primary origin of cultivated plants was created by Vavilov (1932) based on the diversity of the wild relatives of the given species. In this system the European grapevine (*Vitis vinifera* ssp. *sativa*) was classified (together with pistacio and almond) to the Central Asiatic Center.

In the after-glacial Eurasia, the existed woodland grape (*Vitis vinifera* ssp. *sylvestris* GMEL.) spread in whole Europe, and existed even in the southern part of Scandinavia. Man liked its fruits in its natural territory, collected and consumed them. The first *Vitis vinifera* type seeds (long seeds with well-developed “beak”) were found between the excavation finds originating from the 2nd millennium BC. Keeping to west and south, the *Vitis vinifera*-like seed findings turned up gradually from later and later ages. This proves that once the *Vitis vinifera* ssp. *sylvestris* was taken into cultivation from the Trans-Caucasus by the peoples of the ancient Asia. Later the already *Vitis vinifera* was received by the peoples of the antique West-Asia and the people, who lived in the islands of the Aegean-see, spread it on the northern and southern bank of the Mediterranean-see (Kozma, 1991).

According to Terpó (1986) the *Vitis vinifera* ssp. *sativa* is not uniform, but the progeny of more original grape species, the main fundaments between the *Vitis vinifera* ssp. *sylvestris* GMEL. could be the hermaphrodite flowered *V. hissarica* and the *V. nuristanica*. In 1988 he developed a new intraspecific system of *Vitis vinifera* ssp. *sylvestris* GMEL. The substance of his taxonomy was that he sorted the woodland grapes into subspecies based on the hairs of the leaves, and into varietas based on the shape of the leaves. He deduced the eco-geographical groups (convarietas) of *Vitis vinifera* ssp. *sativa* directly or indirectly from these varieties (Jahnke et al., 2014).

Figure 1. Grapevine flower types: hermaphrodite (a), female (b) and male (c) flower (Bényei et al., 1999).

The ancient cultivars of *Vitis vinifera* ssp. *sativa* were classified in three con-varieties pontica, orientalis and occidentalis by Negrul (1969). In his work he pointed, that the crosses between cultivars of different con-varieties lead to valuable types: those between pontica and orientalis gives some promising wine types; and those of orientalis x occidentalis gives early-ripening types; those of occidentalis x pontica segregates and gives some high-quality wine types.

Accordingly this geographical cultivar groups (con-varieties) of *Vitis vinifera* ssp. *sativa* were not likely to have simultaneously developed, but they formed from the different woodland grape types side by side, or crossing one another respectively, as follows: First the pontican cultivar group (convar. pontica) developed in West- and East-Georgia and in Asia Minor. Its initial form could be the local woodland grape, the *Vitis vinifera* ssp. *sylvestris* GMEL. var. *balcanica*, *Vitis vinifera* ssp. *sylvestris* GMEL. var. *typica* (var. *sylvestris*). Inside the eastern cultivar group (convar. orientalis), the subconvar. *caspiaca* was born in the grape-growing countries of the antique Asia Minor, from the woodland grapes near the places bordering on the Caspian-lake (*Vitis vinifera* ssp. *sylvestris* GMEL. var. *abberans*). The origin of the convar. orientalis subconvar *antasiatica* date from the period later. The hybrids of the pontican cultivars and the local woodland grapes (*Vitis vinifera* ssp. *sylvestris* GMEL.) were the starter forms of the western (convar. occidentalis) cultivars (Kozma, 1991).

The *Vitis vinifera* ssp. *sylvestris* GMEL. in Hungary is a protected species (Farkas, 1999). The quest and reservation of its populations are significant in terms of nature conservation and reserve of biodiversity as well. As pointed before, it is supposed, that this species itself, or crossing with other species could be the progenitor of the European grapevine (*Vitis vinifera* ssp. *sativa*). The ex situ conservation of the quested individuals has a great importance in the practical point of view as well, as they can serve as a resistance source in the future breeding programs.

Seed proteins and enzymes (AcP, ADH, EST, G-6-PDH, MDH, PGM, POD) from several cultivars and wild ecotypes of *Vitis vinifera* ssp. *sativa* have been used to evaluate taxonomic differences between *V. vinifera* ssp. *sativa* and *sylvestris*. Only total proteins in the pH range of 4.0-5.5 and AcP, EST and G-6-PDH were useful for genotype differentiation. The cluster analysis (UPGMA), based on Jaccard genetic distance and determined on the presence/absence of electrophoretic profiles, reveals 2 distinct groups, supporting the hypothesis of the authors that *V. sativa* and *V. sylvestris* should be regarded as 2 separate taxa (Scienza et al., 1994. in Jahnke et al. 2012).

Isozyme polymorphism of mature leaves of woodland grape accessions from south-western Turkey was studied by polyacrylamide gel electrophoresis (PAGE) of Acid phosphatase (ACP), Catechol oxidase (CO), Glutamate oxalacetate transaminase (GOT), Malate dehydrogenase (MDH), and peroxidase (PER) enzymes. GOT was monomorphic with two isozyme bands. Polymorphism was detected in the case of PER, CO, ACP and MDH (Söylemezoglu et al., 2001).

The microsatellite analysis of the grape can be traced back to the early nineties. A lot of SSR loci were identified and characterised in grapes (Thomas and Scott, 1993; Scott et al., 2000; etc.) and were mapped (Adam-Blondon et al., 2004.; Constantini et al., 2007).

The characterisation of grapevine cultivars by microsatellite DNA markers in Europe in the framework of an international cooperation called GENRES 081 (European Network for Grapevine Genetic Resources Conservation and Characterisation) was carried out between 1997 and 2002. In this research programme 6 microsatellite primer pairs were determined and

suggested for the characterisation of cultivars. An European project The GRAPEGEN06 which can be considered as the continuation of the GENRES 081 project started in January 2007. The main objective of GrapeGen06 was to contribute to the successful long term preservation of the *Vitis* genetic resources for the use of future generations.

The microsatellite analyses of *Vitis vinifera* ssp. *sylvestris* accessions from Hungary had begun about 10 years before. The earliest publications suggest the preservation of the genotypes based on morphological and microsatellite (Bodor et al., 2010) and microsatellite analyses (Jahnke et al., 2014).

Based on the relevant publications a conservation of natural genetic diversity of *Vitis vinifera* ssp. *sylvestris* was suggested for the populations of Tunisia (Zoghalmi et al., 2013), Azerbaijan, Georgia (De Lorenzis et al., 2014) the populations of Zagros mountains (Iran) (Doulati-Baneh et al., 2014) and Italy (Biagini et al., 2012.; Biagini et al., 2014).

A new project started in September 2013 in Hungary aimed in the quest and ex situ conservation of *Vitis sylvestris* GMEL. individuals in the area of Szigetköz and Fertő-Hanság National Park as well, as the morphological description and analyses of them by molecular markers. The results of the planned analyses can go a long way into the clarification of the origin of *Vitis vinifera* ssp. *sativa*, and to the explanation of the development of the convarieties of the European grapevine (Jahnke et al, 2014).

MATERIALS AND METHODS

The woodland grape stocks were labeled with plastic stripes in-situ in the Szigetköz, in 2013. All of the stocks were marked on map, were located and the GPS coordinates were saved. Photos were taken in spring and in autumn of 2013 and 2014 about all of the individuals. In June, 2013 young shoots from the individuals were collected and grafted to rootstocks in Badacsony, Hungary.

Seeds were collected from 5 (genetically identical) female flowered stocks in the Szigetköz, in autumn, 2013. The seedlings were planted outdoor in early spring, 2014, and young shoots of 23 seedlings were successfully grafted.

The plant material (dormant canes) of 20 *Vitis* rootstocks, 16 *Vitis vinifera* ssp. *sativa* varieties, 4 wild wines from Gemenc (Hungary) and 32 *Vitis vinifera* ssp. *sylvestris* accessions originated from the collection of the NAIRC RIVE of Badacsony and Kecskemét (Hungary) and from the collection of the University of Pannonia in Cserszegtomaj (Hungary) for rootstocks.

DNA was extracted from the phloem of the dormant canes with DNA Plant Mini Kit (Quiagen), following the manufacturer's instructions. The amount and quality of DNA was determined spectrophotometrically. The DNA was diluted to a concentration of 10 ng/ml.

Microsatellite (SSR) analysis was performed in 8 loci. Three multiplex polymerase chain reactions were carried out in a total volume of 10 µl containing 5 µl of Hot Start Master Mix (Quiagen, Germany), 0.1-0.4 µM of each primer, and 1µl of template DNA. Forward primers were fluorescently labeled with 6-FAM, VIC, NED or PET as reported in Table 2. The following thermal profile was used: (1) 95°C for 30 min (hot start); (2) 95°C for 30 sec, 55°C for 30 sec (decreased by 1°C in each cycle), 72°C for 30 sec per 30 cycles; (4) 95°C for 30 sec, 55°C for 15 sec, 72°C for 30 sec per 30 cycles; (5) 72°C for 7 min.

* according to Migliaro et al. 2013.

One primer of each primer pairs were fluorescently labeled on the 5' end of the DNA chain according to Migliaro et al. (2013). PCR products were run on a PE-Applied Biosystem 3100 Automated Capillary DNA Sequencer, the length of the products were determined using GeneScan 2.0 software (Applied Biosystem).

Estimates of genetic similarity between pairs were calculated by the Jaccard index (Jaccard, 1908). For the generation of distance matrices and UPGMA dendograms a demo version of MolMarker was used (Györfyné Jahnke and Smidla, 2014).

RESULTS

20 stocks of woodland grapes (*Vitis sylvestris* GMEL.) were found in 3 sites, 2 sites in the Szigetköz, and one near Jánossomorja. In Badacsony 8 of the genotypes of the 20 stocks found in-situ were conserved by clonal propagation (grafting to Teleki 5C rootstocks). 24 seedlings were successfully germinated and grafted to Teleki 5C rootstocks.

The mean number of alleles per locus and mean genotype number in rootstocks were 12.875 and 13.875; in woodland grapes 7.750 and 9.625 and in cultivated grapevines 8.500 and 10.875 respectively. The H (Heterosigosity) and PIC (Polimorphic Information Content) values in rootstocks were 0.7266 and 0.8440; in woodland grapes 0.625 and 0.5682; while among cultivated grapevines it was 0.7473 and 0.7781 respectively.

The detailed results of SSR analyses are presented in Table 4.

Based on the results UPGMA dendrogram was constructed, which is presented in Figure 5.

DISCUSSION

The summary statistics of loci in rootstocks, woodland grapes and cultivated grapevines shows that the woodland grape accessions has the lowest genetic diversity, followed by the cultivated varieties. The highest genetic diversity was found in rootstocks.

Similarly low genetic diversity was observed with 7.56 alleles per locus, and 0.464 heterosigosity in the woodland grapes of the Geisenheim collection in Germany (Bitz et al., 2015). Low genetic diversity was observed in Austria as well (Regner et al. 2004).

Contradictorily quite high heterosigosity (0.67) was observed In Iranian wild woodland grape (*Vitis vinifera* ssp. *sylvestris*) populations. The study of the genetic diversity of woodland grapes and cultivated varieties of Azerbaijan and Georgia an east-to-west distribution from Caucasus to Europe confirming the suggestion of Myles et al. (2011) and Imazio et al. (2013).

Figure 5. UPGMA dendrogram of the accessions based on SSR results.

In this study, the low genetic diversity of *Vitis vinifera* ssp. *sylvestris* shows that the population of the Szigetköz (Hungary) may originated from the Western-European populations.

Based on the SSR results presented in Table 4, UPGMA dendrogram was constructed. The main groups (*V. vinifera* ssp. *sylvestris*, *V. vinifera* ssp. *sativa*, and rootstocks) mainly form 5 distinct groups. *Vitis vinifera* ssp. *sylvestris* GMEL. accessions form two distinct group in the dendrogram. The rootstocks Aramon Ganzin N1 and (N2 (*V. vinifera* x *V. rupestris*), shows similarity to *Vitis vinifera* ssp. *sativa* variety ‘Cserszegi fűszeres’, which is not surprising taking into account the hybrid origin of this accessions.

Most of the *V. vinifera* ssp. *sativa* varieties forms a large group with most of the *V. vinifera* ssp. *sylvestris* genotypes, but the two subspecies (*sativa* and *sylvestris*) forms distinct subgroups. Most of the rootstock accessions form an distinct group.

The *Vitis vinifera* ssp. *sylvestris* genotypes form distinct groups and show similarity with *Vitis vinifera* ssp. *sativa* genotypes, which clearly shows their true-to-typeness.

The 4 in-situ conserved genotypes of the Gemenc forest (Hungary) fall into 2 groups. Gemenc 2 and Gemenc 3 shows similarity to both *sativa* and *sylvestris* groups, supposing their *Vitis vinifera* ssp. *sylvestris* or hybrid (*sativa* x *sylvestris*) origin.

The other group of Gemenc 1 and Gemenc 4 is in the rootstock group, which probably shows their hybrid (*V. sylvestris* x *V. ripara*) origin.

To clarify these questions further genetic, molecular and morphological analyses are planned. Our results support – as suggested by Bodor et al. (2010) - the further quest, ex-situ and in-situ preservation and analyses of the *Vitis vinifera* ssp. *sylvestris* germplasm in Hungary.

ACKNOWLEDGMENT

This research was funded by the Hungarian Scientific Research Fund (project no. PD-109386).

ABSTRACT

Two major cherry species are grown for their fruit, the diploid sweet cherry and the tetraploid sour cherry. Cherries are characterized by high genetic diversity mainly due to their self-incompatibility propagation system. Estimation of the species phenological and genetic diversity has been performed using a number of different traits and marker systems including morphological and anatomical characteristics, as well as isoenzyme and molecular markers. Different molecular markers have been used, spanning from restriction fragment length polymorphisms (RFLPs) to single nucleotide polymorphisms (SNPs), simple sequence repeat (SSR) markers being the most frequently. Moreover, molecular markers have also been used to mark and trace specific agronomic traits, such as self-(in)compatibility (S-alleles) or fruit weight thus developing functional markers. The markers reviewed herein will be useful not only for monitoring the genetic diversity in cherry breeding programs, but also for gene conservation, while these or other markers may permit marker-assisted selection for favorable agronomic traits.

Keywords: sweet cherry, sour cherry, genetic diversity, molecular markers, S-allele, morphological markers

INTRODUCTION

Sweet (*Prunus avium*) and sour cherry (*P. cerasus*), (Rosaceae), are highly valued for their excellent quality fruits and wood. Sour cherry is a tetraploid species ($2n=4x=32$) originated through natural hybridization between sweet cherry ($2n=2x=16$) and the wild tetraploid ground cherry (*P. fruticosa*) (Rakonjac et al., 2010).

The cherry world production faced an increase in terms of production in many new and traditional regions. Sweet cherries are one of the few remaining seasonal fruit crops as it cannot be stored for a long time, and in many markets no other item creates as much seasonal in-store activity as fresh cherries (Kappel et al., 2012).

A ‘genetic marker’ is a DNA sequence associated with a gene which has a clear effect in the phenotype, but a genetic marker can also be associated with a non-coding part of the genome (which does not contribute to the phenotype). Genetic diversity studies in cherries have been performing by various biochemical (e.g., isoenzyme) and DNA-based (molecular) markers. Different molecular markers have been applied in cherries, such as restriction fragment length polymorphism (RFLP) and several PCR-based techniques. Among these techniques, randomly amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), microsatellites or simple-sequence repeats (SSR), inter-simple sequence repeats (ISSR), single nucleotide polymorphisms (SNP) and functional markers (detecting the molecular changes behind a specific trait) have been used. The aim of this review is to present an overview of the different techniques used and results obtained for the assessment of cherry genetic diversity, and to assess their applicability in breeding. The implications of novel genomic technologies such as next generation sequencing (NGS) and Genotyping by Sequence (GBS) are also discussed.

MORPHOLOGICAL TRAITS

Morphological traits have been traditionally used for species description and taxonomical identification. Morphological traits are the result of genetic x environment interaction and usually are controlled by more than one gene, presenting a continuous variability that is correlated with the number of genes involved (Ayala, 1982, El-Esawi et al., 2012).

Many studies indicated that fruit and leaf traits are crucial factors in phenotyping and morphologically characterizing the diversity in sweet cherry breeding materials (Antonius et al., 2012, Ganopoulos et al., 2011b, Hjalmarsson and Ortiz, 2000, Lacis et al., 2009a, Rakonjac et al., 2010). Principal component analysis (PCA) has been employed to determine the relationships among cultivars, to study correlations among tree traits and to evaluate sweet cherry (Beyer et al., 2002, Christensen, 1974, Ganopoulos et al., 2011b, Hjalmarsson and Ortiz, 2000, Khadivi-Khub, 2014, Lacis et al., 2009a, Petruccioli et al., 2013, Rodrigues et al., 2008, Sánchez et al., 2008), sour cherry (Hillig and Iezzoni, 1988, Iezzoni and Pritts, 1991, Krahel et al., 1991, Rakonjac et al., 2010) and *Cerasus* (Khadivi-Khub et al., 2012, Shahi-Gharahlar et

al., 2010). Recently, Ganopoulos et al. (2016) estimated the diversity of morpho-physiological traits in a worldwide collection of sweet cherry cultivars (n=146) in Greece using multivariate analysis. They found that the characterized sweet cherry collection had a high potential for specific breeding goals and suggested that a multivariate statistics approach taking into account both the genetic and the phenotypic data could be of the utmost importance for the analysis of the diversity of GeneBank collections. Furthermore, the same group examined the morpho-physiological diversity in a diverse collection of sour cherry cultivars using multivariate analysis and revealed significant diversity regarding the morpho-physiological traits used.

ISOENZYME ANALYSIS

Isoenzymes are different forms of an enzyme, their difference being in their amino acid sequences, yet they catalyse the same biochemical reaction. Amino acid changes in the different forms of an enzyme cause differences in their polarity and structure, which result in changes of their electrophoretic mobility which forms the basis of their separation and visualization. Isoenzymes may be encoded by genes at different loci or different alleles at the same locus (known as alleloenzymes or allozymes). The detection of isoenzymes was the first molecular marker strategy to be used, because of their co-dominant gene expression and very good reproducibility (Santi et al., 1990, Arulsekhar and Parfitt, 1986, Cerezo and Arus, 1989).

(Granger et al., 1993) used 10 isozymes which allowed the identification of 76 sweet cherry varieties despite the fact that some of them which shared the same morphological characters, were previously considered as the same variety. The following enzyme systems have been applied to study polymorphism in 36 sweet, sour and ground cherry cultivars: isocitrate dehydrogenase (IDH), phosphoglucosomerase (PGI), phosphoglucosomutase (PGM), shikimate dehydrogenase (SKDH), 6-phosphoglucosomate dehydrogenase (6-PGD), leucine aminopeptidase (LAP) and malate dehydrogenase (MDH) (Beaver et al., 1995). Beaver et al. (1995), suggested that sour cherry is more polymorphic than sweet cherry, which might be attributed to its allotetraploid nature. Isoenzymes have also been used by (Santi et al., 1990) and (Frascaria et al., 1993) for the identification of *P. cerasus* and *P. avium*. Furthermore, (Corts et al., 2008) applied five isozymes in a collection of 17 sweet and sour cherry cultivars, however their study showed low isoenzymatic polymorphism.

GENETIC DIVERSITY STUDIES WITH MOLECULAR MARKERS

Sweet Cherry

Different molecular markers have been used in cherries genetic diversity studies. (Stockinger et al., 1996) and (Gerlach and Stösser, 1997) have applied RAPD markers and deemed them suitable for cultivar identification in sweet cherry. However, the method of choice in the last 15 years regarding studies on cherries genetic diversity is SSR markers (Cantini et al., 2001, Dirlwanger et al., 2002, Wünsch and Hormaza, 2002, Schueler et al., 2003, Bianchi et al., 2004, Vaughan and Russell, 2004, Aka Kaçar et al., 2005, Ohta et al., 2005, Hölten and Gregorius, 2006, Pedersen, 2006), due to their stability, co-dominance and multi-allelism.

Peach (*Prunus persica*) was the donor of the most commonly used SSR primers in *Prunus* sp. (Dirlewanger et al., 2002), sweet cherry (Sosinski et al., 2000, Dirlewanger et al., 2002) and sour cherry (Lacis et al., 2009). Moreover, several SSRs have been developed later in order to determine genetic relationships in all *Prunus* species (Lacis et al., 2009b, Antonius et al., 2012). Due to the fact that SSRs are transferable among *Prunus* species, the same SSR primers are used in order to detect intra-species variation in related species (Dirlewanger et al., 2002, Wünsch and Hormaza, 2002).

(Ganopoulos et al., 2011b) assessed the genetic diversity of 21 Greek sweet cherry cultivars with 15 microsatellite markers and detected a total of 92 alleles (mean number of alleles per locus=5.80). (Guarino et al., 2009) examined a collection of 60 sweet cherry accessions of an Italian germplasm to estimate genetic diversity and to identify genetic relationships among ancient accessions using a set of 28 microsatellite markers. The expected heterozygosity (H_e) ranged from 0.031 to 0.822 while the total probability of identity was 5.59×10^{-16} . (Sharma et al., 2015) determined the genetic diversity of 24 Czech sweet cherry cultivars using 16 microsatellite markers generating 70 alleles. The observed heterozygosity value of these cultivars ranged from 0.25 to 0.96 with an average of 0.72. (Farsad and Esna-Ashari, 2016) characterized 23 Iranian sweet cherry cultivars considered for breeding programs using 16 polymorphic microsatellite markers producing 177 alleles that varied from 4 to 16 alleles with a mean heterozygosity value of 0.82. (Stanys et al., 2012) characterized the genetic diversity of 31 Lithuanian sweet cherry cultivars with 14 microsatellite markers and found a H_o value of 0.65. These results are in accordance with the values obtained by other studies for sweet cherry: 0.59 (Schueler et al., 2003), 0.49 (Wünsch and Hormaza, 2002), 0.50 (Clarke and Tobutt, 2003), 0.61 (Vaughan and Russell, 2004), 0.71 (Ganopoulos et al., 2011b).

One of the recent advances in the field of PCR based methods is high resolution melting analysis (HRM), which is a powerful method for fingerprinting, detection of mutations, SNPs, polymorphisms and epigenetic differences in distinct DNA samples (Wittwer, 2009, Ganopoulos et al., 2011a). This technique is becoming the method of choice as it incorporates unique advantages over other genotyping methods: it is cost-effective, fast, simple, powerful and suitable for high-throughput and accurate analysis. (Fernandez i Marti et al., 2012) applied HRM analysis to SNP genotyping a collection of 104 sweet cherry cultivars. They found a mean value of six alleles per locus, the observed heterozygosity (H_o) ranged from 0.14 to 0.66 while the expected heterozygosity (H_e) was ranged from 0.38 to 0.73. Moreover, (Ganopoulos et al., 2013) described the application HRM analysis for the characterization of PCR products and the identification of nine gene-based SNPs for distinguishing the main Greek sweet cherry cultivars. They found a H_e average value of 0.518 based on nine SNPs. The combined power of discrimination for the SNP markers was 0.999. Authors suggested that the ability of HRM to accurately discern nucleotide changes in a DNA sequence made it a cost- and time-effective alternative to traditional sequencing for the detection of gene-based SNPs.

Recently, (Campoy et al., 2016) genotyped a total of 210 genotypes including modern cultivars and landraces from 16 countries by using the RosBREED cherry 6 K SNP array v1. They found higher diversity in landraces compared to bred cultivars. These results were in agreement with the loss of diversity associated to breeding.

Sour Cherry

Various molecular markers and associated techniques are available today for investigation of plant germplasm and SSR markers have been widely used for genetic diversity in sour cherry (Cantini et al., 2001, Canli, 2004, Pedersen, 2006, Lacis, 2010, Antonius et al., 2012, Najafzadeh et al., 2016).

(Antonius et al., 2012) collected 77 cultivars established into the Finnish national sour cherry germplasm collection and studied its genetic diversity with nine microsatellite markers which produced 72 alleles in total. Furthermore, (Clausen et al., 2013) found no intra-cultivar variation in Denmark sour cherry clones by using 10 microsatellite markers. Recently, (Najafzadeh et al., 2016) used 19 microsatellite markers in order to investigate the genetic diversity of 12 Iranian sour cherry genotypes generating 148 alleles. Previously, (Cantini et al., 2001) demonstrated that 10 microsatellite markers could be used to differentiate among all but two of the 59 tetraploid cherry accessions examined in the USDA/ARS germplasm collection. The primer pairs amplified in their study ranged from 4 to 16 alleles with a mean of 10.7 alleles/locus.

(Peace et al., 2012) used a cherry-peach comparative genomics strategy to develop a moderate-density cherry SNP array relevant for sweet and sour cherry breeding germplasm based on SNPs discovered using next generation sequencing platforms. The array was evaluated using panels of sweet ($n = 269$) and sour ($n = 330$) cherry breeding germplasm.

S-Allele Genotyping

Many *Rosaceae* species have a distinct reproduction system that is characterized by self-incompatibility. This mechanism which restricts self-fertilization and promotes outbreeding controlled by alleles located at a particular locus, the *S*-locus. For incompatibility to occur an *S*-allele in the pollen tube needs to be in common with either of the two alleles in the stylar parent; in such as case, the pollen tube will stop developing and will not fertilize the egg (Chasan, 1991). The end result is that pollen from the same plant is rejected (self-incompatibility) and this is extended to any fertile pollen from any other cultivar that shares an *S*-allele with the stylar (De Nettancourt, 2001). Thus, all commercial cultivars which share *S*-alleles need the presence of trees, which will serve as efficient pollinators. Relevant research has led to the identification of self-incompatible and self-compatible genotypes (Lansari and Iezzoni, 1990, Yamane et al., 2001, Hauck et al., 2002). Due to the fact that sour cherry is a tetraploid hybrid of diploid sweet cherry and tetraploid ground cherry, the self-incompatibility mechanism appears to be conserved only in certain genotypes.

Sweet and sour cherry share many of the naturally occurring *S*-haplotypes. Yet there are other *S*-haplotypes like the S_1 , S_6 , and S_{13} , which have lost either pollen or stylar function and are present in sour cherry (Hauck et al., 2006, Tsukamoto et al., 2006). In terms of genetic information, the loss of function was due to DNA sequence alterations upstream of the *S-RNase*, *SFB* or *S-RNase* sequences.

Due to the *S*-incompatibility system most, if not all sweet cherry cultivars are self-incompatible, thus they require the presence of pollinators from specific compatible varieties. The standard practice in commercial orchards is to plant at every third position in every third

row for standard size trees, a pollinizer tree which belongs to a different incompatibility group. Yet this practice although it uses the minimum number of pollinator trees while ensuring at the same time the effective pollination and thus production has a major draw-back which is the loss of yield due to the presence of trees that do not fruit.

The S-incompatibility system allowed after the cloning and sequencing of the *S-RNase* locus from sweet cherry (Tao et al., 1999) the development of PCR methods suitable to distinguish the S-allele types. A large number of PCR primers has become available for S-RNase genotyping (Sonneveld et al., 2005, Wiersma et al., 2001), including the most important S-allele, the S_4' allele which confers self-compatibility (Ikeda et al., 2004). To date more than 20 S-RNases have been recognized leading to the development of 23 incompatibility classes and two SC classes containing the S_4' allele. The 23 incompatibility groups include only 10 S-alleles ($S_1 - S_7, S_9, S_{12}, S_{13}$) (Tobutt et al.).

The S-locus has also been used to investigate local variability of sweet cherries in many countries, for instance in Croatia (Ercisli et al., 2012), Germany (Schuster, 2012, Schuster et al., 2007), Greece (Ganopoulos et al., 2010), Latvia (Lacis et al., 2008), Sicily (Marchese et al., 2007), Spain (Cachi and Wünsch, 2014, Wünsch and Hormaza, 2004, Gisbert et al., 2008), Turkey (Ipek et al., 2011, Szikriszt et al., 2013) and wild cherry populations from Belgium (De Cuyper et al., 2005), Turkey (Szikriszt et al., 2013) and the UK (Vaughan et al., 2008). Certain S-haplotypes showed increased frequency in certain countries like haplotype S_{16} which was found in high frequency in the Sicilian germplasm, or the S_1 haplotype in cultivars from Germany (Schuster et al., 2007), and S_2 in Turkey (Ipek et al., 2011, Szikriszt et al., 2013). However, in many cases, the same S-haplotype was found in local material from distant European regions. In nineteen Greek cultivars, four alleles, S_1, S_3, S_4 , and S_9 were widespread and together were responsible for 85% of the S-haplotypes (Ganopoulos et al., 2010). Haplotype S_6 was highly frequent in genetic resources from Latvia and Scandinavia (Lacis et al., 2008), but is also very frequent in sweet cherries from the 'Jerte Valley' in Spain (Wünsch and Hormaza, 2004). (Cachi and Wünsch, 2014) performed the S-genotyping of 73 Spanish sweet cherry varieties and found that the S-haplotypes S_3, S_6 and S_{22} were the most frequent while the haplotype S_{16} was only found in the Balearic Islands. Furthermore, the S_{12} allele which was identified in wild cherry from Belgium and the UK (De Cuyper et al., 2005, Vaughan et al., 2008) was also present in high frequency in local material from Mediterranean countries like Croatia, Greece, Turkey and Spain (Gisbert et al., 2008, Ipek et al., 2011, Ercisli et al., 2012). On the contrary, allele S_{12} is absent in the native Greek populations (Ganopoulos et al., 2012) and in the collection of Greek sweet cherry cultivars (Ganopoulos et al., 2010).

Recently, S-alleles in 47 sweet cherry cultivars were recognized from local material of Central and Eastern Europe, and specifically mostly from Ukraine and the Czech Republic, 43 S-genotypes were found for the first time and the analyzed sweet cherry cultivars were assigned to 20 of the existing incompatibility groups (Lisek et al., 2015).

As S-incompatibility requires the presence of pollinators which reduces potential yield, sweet cherry breeding has focused (among others) in the production of commercial self-compatible varieties. Marker assisted selection for early detection of SC progeny is one possibility in sweet cherry breeding programs as the markers can identify the pollen-part mutant S_4' from its wild-type allele. This mutant allele has a four bp deletion in the *SFB4'* region (Sonneveld et al., 2005, Ushijima et al., 2004) and thus can be identified and distinguished from

its wild-type allele by a dCAPS marker system (Ikeda et al., 2004). However, unlike sweet cherry, individual sour cherry seedlings would need to be screened for multiple alleles.

CONCLUSION

The value of developing markers and the sequencing of whole genomes is the provision of a wealth of knowledge and data which can be used to understand basic molecular functions, and regulation of gene expression, especially for genes responsible for traits of agronomic interest in breeding programs. Thus, this knowledge could be translated into targeted and successful breeding program approaches. The development of saturated genetic maps enhanced by novel genetic markers has allowed the identification of chromosomal positions where disease resistance and fruit quality genes are located. Marker assisted selection can now be used in breeding programs.

The technological progress in sequencing and especially in next generation sequencing (NGS) has extended so far that genotyping by sequencing (GBS) is now possible (Davey et al., 2011). This leads to new pathways for genetic diversity management, particularly for conservation and survey of large populations. It is not far the day where new technologies such as NGS and GBS would let breeders and scientists to determine population characteristics establishing genome or nucleotide diversity. GBS would probably unlock the potential for global and quantitative management of genetic diversity, and let us predict an *a priori* genetic resource management.

ABSTRACT

Soybean purple seed stain (PSS) causes seed decay and purple seed discoloration, resulting in overall poor seed quality and reduced market grade and value. It is a prevalent soybean disease that also affects seed vigor and stem establishment. PSS is caused by the fungus *Cercospora kikuchii* and other *Cercospora* spp. The most common symptom of this disease occurs on the seed. Infected seeds may appear healthy or have discoloration in seed coat varying from pink to light or dark purple spots with range in sizes from a small speck to the entire seed coat. Warm and humid environments favor pathogen growth and disease development. Management strategies for this disease include crop rotation with non-legume or non-host crops, fungicides applications, and tilling the soil to disrupt spore dissemination. Along with these strategies, the use of resistant cultivars may provide more reliable and economical control of PSS, especially when environmental conditions are conducive for disease development. In this chapter, general information about the PSS and an overview of research on germplasm screening and genetic resistance are presented and discussed.

Keywords: soybean, purple seed stain, *Cercospora kikuchii*, seed quality

INTRODUCTION

Purple seed stain (PSS) of soybean (*Glycine max* (L) Merr.) causes seed decay and purple seed discoloration, resulting in overall poor seed quality and reduced market grade and value (Wilcox and Abney 1973; Roy and Abney 1976; Walters 1980; Yeh and Sinclair 1982; Ward-Gauthier, et al. 2015). It is a prevalent disease that also affects seed germination, seed vigor and stand establishment (Pathan et al. 1989; Schuh 1999).

PSS was first reported in Korea in 1921 and was described as a purple discoloration of the seeds (Suzuki, 1921). In 1925, Matsumoto and Tomoyasu found a fungus “which seemed to belong to the genus *Cercospora*” growing in the purple seed coats of soybeans (Matsumoto and Tomoyasu, 1925). In the United States, PSS was first documented in Indiana in 1924 (Gardener, 1926) and then in North Carolina in 1927 (Lehman, 1928). At the present time, PSS occurs in most soybean production areas worldwide (Roy and Abney, 1976; Grau et al., 2004). Soybean yield loss in the United States due to PSS has been reported at 85.2 thousand metric tons (Wrather et al. 2010).

DISEASE SYMPTOMS

The most common and easily recognized symptom of PSS occurs on the seed (Schuh, 1999). Infected seeds may appear healthy or have discoloration varying from pink to light or dark purple spot on the seed coat. The size of discoloration ranges from small pinpoint spot to covering the entire seed coat (Figure 1). Many small cracks are usually found in the discolored areas on the seed coat making seeds appear rough and dull.

In addition to symptoms occurring on the seed, the disease develops on pods, stems, and leaves. Cerospora leaf blight (CLB) in soybean is an important disease associated with PSS (Ward-Gauthier et al., 2015). In general, leaf symptoms do not show until late in the season when plants reach R5 to R6 growth stages. In the field, the first visible symptom of CLB occurs on the top surface of leaves exposed to the sun with light purple discoloration. The leaves appear leathery and 'sunburned'. The discolored areas may be small, discrete, and form irregularly shaped spots at the beginning. As the disease progresses, the infected leaf area expands and deepens in color to reddish-purple or bronze. In some cases, both upper and lower surfaces of entire leaves can be completely discolored. Severe infection causes necrosis of leaf tissue resulting in defoliation.

THE CAUSAL AGENTS

It has been reported that both PSS and CLB are caused by the fungal pathogen *Cercospora kikuchii* (Tak. Matsumoto & Tomoy.) M. W. Gardner (Walters, 1980). The scientific classification of *C. kikuchii* is described by Wikipedia (https://en.wikipedia.org/wiki/Cercospora_kikuchii) as follows: “Kingdom: Fungi; Phylum: Ascomycota; Class: Dothideomycetes; Subclass: Dothideomycetidae; Order: Capnodiales; Family: Mycosphaerellaceae; Genus: *Cercoseptoria*; Species: *C. kikuchii*.” The binomial name is

Cercospora kikuchii (Matsumoto & Tomoy, 1925)". The vegetative compatibility groups and the population structure of *C. kikuchii* have been investigated (Cai and Schneider, 2005; 2008).

Figure 1. Symptoms of purple seed stain in soybean.

It was first documented in 1957 that *C. kikuchii* produces a non-host specific phytotoxin (Kuyama and Tamura, 1957). The toxin is named cercosporin, a red perylene quinone pigment. It has a molecular weight of 534 and is photoactivated (Upchurch et al., 1991). Later, cercosporin was found in different *Cercospora* spp. (Assante, et al., 1977; Lynch and Geoghegan, 1977). Since cercosporin has been isolated from necrotic lesions of infected plants, studies on the role of cercosporin in PSS and CLB disease development were begun. Upchurch et al. (1991) used *C. kikuchii* mutants that blocked cercosporin synthesis to demonstrate that cercosporin was an important factor in the pathogenicity for infection of soybean (Upchurch et al., 1991).

In past decades, *C. kikuchii* was thought to be the only causal agent of PSS and CLB. Recently, more *Cercospora* species were reported to infect soybean across the Americas (Soares et al., 2015). Analysis of eight nuclear genes and a mitochondrial gene; surveys of amino acid substitutions; assessment of cercosporin production; and multiple *Cercospora* spp. including *C. cf. flagellaris* were reported to be associated with PSS and CLB (Soares et al., 2015). Some *Cercospora* isolates that caused PSS but not CLB have been found (S. Li, unpublished). Identification of all *Cercospora* species that cause PSS and/or CLB is underway. Investigation of the genetics basis of pathogenicity related genes using genomics approaches will aid in the development of new control strategies for the *Cercospora* pathogens.

DISEASE DEVELOPMENT AND EPIDEMIOLOGY

Development of PSS and CLB is influenced by environmental factors, such as relative humidity and composition and pH values of the substrates, as well as by light/photoperiod. It was reported that a minimum dew period of 18 hours is required for leaf and pod infection by *C. kikuchii* (Schuh, 1991). It also was reported that germination of *C. kikuchii* conidia was significantly lower at 24 h of light (35.6%) compared to photo periods of 24 h of light/24 h of dark (87.7%), 12 h of light/12 h of dark (88.8%), and 12 h of dark/12 h of light (89.5%), (Schuh, 1993). A photo period of 12 h of dark and 12 h of light was most conducive to infection. High-relative humidity (>95%) resulted in higher disease severity (Schuh, 1993).

In addition, seed infection and disease development are favored by high temperature and humidity during the early reproductive stages of soybean (Schuh, 1993). Leaf and pod infection occur at temperatures ranging from 15 to 32°C (Schuh, 1992), although optimum infection occurs at 25°C (Schuh, 1991).

DISEASE MANAGEMENT

Several strategies have been used to control the disease, such as tillage, crop rotation (Almeida, et al., 2001), fungicide applications at pod-filling stages (TeKrony, ET AL., 1985), and the use of genetic resistance (Jackson, et al., 2006; 2008; Ploper, et al., 1992; Srisombun and Supapornhemin, 1993; Wilcox, et al., 1975). The use of *C. kikuchii*-resistant genotypes to control the disease is economical and environmentally friendly.

Soybean Germplasm Screening for Resistance to Purple Seed Stain

To identify sources of resistance to PSS and CLB, a total of 123 plant introductions (PI) from 28 different countries, representing maturity groups (MG) III, IV, and V, were screened (Alloatti, et al., 2015b). Incidence of *Cercospora* leaf blight (% CLB), visual PSS (% PSS), and seed infected by *C. kikuchii* (% *C. kikuchii*) in harvested seed were determined. It was reported that in 2007, % *C. kikuchii* ranged from 2 to 51% for MG III, 2 to 35% for MG IV, and 0 to 33% for MG V. In 2008, % *C. kikuchii* ranged from 0 to 45% for MG III, 1 to 71% for MG IV, and 0 to 15% for MG V (Table 1). A total of 4 and 10 PIs from MG III and IV, respectively were identified as resistant to PSS in both years. There were significant positive correlations between inoculated vs. non-inoculated treatments and between % PSS and % *C. kikuchii* infection (Alloatti, et al., 2015b). The PSS resistant plant introductions identified in this study are valuable to breeders in developing resistant cultivars.

In other studies, 42 soybean lines from MG III, IV, and V with different reactions to other diseases in previous trials were tested for their reaction to PSS in field trials in Mississippi, USA (Li and Sciumbato, 2011a; b; 2012). Significant differences ($P \leq 0.01$) in seed infection by *C. kikuchii* were observed among soybean lines ranging from 2.0% to 16.0%. Results from tests of MG III soybean lines indicated that PI 578486 and PI 437482 were among the lines with lowest percentages of seed infection, while cultivar AG4403 had the highest percentage of seed infection. Of 14 lines tested, four lines had less than 5% seed infection (Li and

Sciumbato, 2012). Among MG IV soybeans, percentage of seed infection by *C. kikuchii* ranged from 3.0% to 16.5%. Soybean lines PI 346307 and PI 80479 were among the lines with lowest percentages of seed infection, while PI 58765 had the highest percentage of seed infection. Of 14 lines tested, five lines had less than 5% seed infection (Li and Sciumbato, 2011a). Results from the test of MG V soybean indicated that PI 407749 and PI 381659 were among the lines with lowest percentages of seed infection, while PI 417098 had the highest percentage of seed infection. Of 14 lines tested, four lines had less than 5% of seed infection (Li and Sciumbato, 2011b).

Evaluation of Soybean Cultivars for Reaction to *Cercospora* Leaf Blight

Cercospora leaf blight (CLB) has become a prevalent disease in many soybean production areas, especially in Louisiana, U.S.A. Cai et al. (2008) found that the Louisiana population of *C. kikuchii* was dominated by a new lineage that differed from those collected in other locations at earlier times. Then, they tested whether the dominance of the new lineage was caused by higher aggressiveness, and screened soybean cultivars for resistance to CLB. Representative isolates from both lineages were used individually to inoculate six soybean cultivars in the greenhouse. Unexpectedly, the new lineage was less aggressive than the old lineages. Three virulence groups were defined in this pathogen based on correlation of the aggressiveness of individual isolates on soybean cultivars. Results from the test of eleven soybean cultivars for disease reaction at two locations over 3 years in the field identified two cultivars, AG5701 (Asgrow) and TV59R85 (Terral), that were among the more resistant cultivars to CLB both in the greenhouse and in the field (Cai et al., 2009).

GENETIC RESISTANCE

Using genetic resistance is one of the most efficient and least expensive ways to control PSS and CLB. There are reports about host resistance to PSS. Srisombun and Supapornhemin (1993) found that resistance to PSS in soybean cultivar SJ.2 was controlled by a single dominant gene. Ploper et al. (1992) identified that PI 417274, PI 417460, and Gnome were resistant to both *Phomopsis* spp. and *C. kikuchii*, while PI 80837 was reported to possess resistance to PSS (Wilcox et al. 1975; Ploper et al. 1992). Heritability estimates of 0.91 in the F₂ and 0.51 in the F₃ generation for resistance to *C. kikuchii* were found for the progeny of the cross ‘Amsoy’ x PI 80837, which indicated a strong genetic component for resistance (Wilcox et al. 1975). Jackson et al. (2006) reported that PSS resistance was conditioned by a single dominant gene in PI 80837. The major PSS gene (*Rpss1*) was mapped on Chr. 18 between markers Sat_308 (6.6 cM) and Satt594 (11.6 cM) (Jackson 2004; Jackson et al. 2008).

Table 2. Analysis of variance for % PSS and % *C. kikuchii* infection in two soybean F_{2:5} populations derived from AP 350 x PI 80837 and PI 80837 x MO/PSD-0259 (Alloatti et al., 2015a)

	% PSS ^a					% <i>C. kikuchii</i> infection ^b

^a % seed with purple seed stain based on visual assessment; DF = Degree of freedom;

^b % seed with *C. kikuchii* infection based on PDA plating; DF = Degree of freedom.

Recently, Alloatti et al., (2015a) investigated the inheritance of PSS resistance and identified microsatellite markers tightly linked to the major resistance gene *Rpss1* in PI 80837. In this study, two populations were developed by crossing a PSS resistant line, PI 80837, to PSS susceptible lines AP 350 and MO/PSD-0259. A total of 168 of F_{2:5} lines were grown at Kibler, AR in a randomized complete block design with three replications. Each plot was harvested and seed samples were taken to evaluate the percentages of visual PSS (% PSS) and *C. kikuchii* infection (% *C. kikuchii*). Ranges, LS means, and confidence intervals of the parents were used to classify resistant and susceptible reactions in the F_{2:5} lines for the two variables evaluated.

Significant differences in both % purple seed stain (PSS) and % *C. kikuchii* infection were observed between the resistant and susceptible parents and among the F_{2:5} lines, derived from AP 350 x PI 80837 and PI 80837 x MO/PSD-0259 (Table 2). The % *C. kikuchii* was consistently higher than % PSS among parents and F_{2:5} lines, indicating latent infection in seed. The resistant parent PI 80837 had significantly lower % PSS (3%) and % *C. kikuchii* (6.7%) than the susceptible parents AP 350 (34% PSS, 63.3% *C. kikuchii*) and MO/PSD-0259 (14.7% PSS, 39.0% *C. kikuchii*). LS means for % PSS and % *C. kikuchii* varied from 0.3 to 27.3% and 1 to 50%, respectively for the F_{2:5} lines from AP 350 x PI 80837. The F_{2:5} lines from PI 80837

x MO/PSD-0259 had 0.3 to 26% PSS and 1 to 47% *C. kikuchii*. For the AP 350 x PI 80837 population, the heritabilities for resistance to PSS and *C. kikuchii* were 0.62 and 0.60, respectively. For the PI 80837 x MO/PSD-0259 population, the heritabilities for % PSS and % *C. kikuchii* were 0.72 and 0.67, respectively (Alloatti et al., 2015a).

Alloatti et al. (2015a) also used sixteen SSR markers in a 17.1 cM region on Chromosome (Chr.) 18 to screen the parents and both F_{2:5} populations. Significant differences in % PSS and % *C. kikuchii* were observed for the parents and both F_{2:5} populations. For the two variables evaluated, both populations showed a good fit to a ratio of 15:1 (resistant to susceptible), indicating two dominant genes were involved for resistance. One chromosomal region in the vicinity of Satt115 and Satt340 on Chr. 18 was determined to be associated with the resistance gene *Rpss1* in both populations. These results confirm the presence of a major resistance gene, *Rpss1*, in PI80837 and also indicate an additional putative gene for PSS resistance (Alloatti et al., 2015a).

In future studies, screening the soybean genome with more molecular markers covering other soybean genomic regions to find the location for other gene should be considered. The PSS resistant PI, confirmation of the resistance gene and identification of an additional resistant gene will be valuable for breeders to develop resistant cultivars. Molecular markers linked to the resistance gene will facilitate selection for PSS resistance in future breeding efforts.

SUMMARY

Soybean purple seed stain (PSS) causes seed decay and purple seed discoloration, resulting in overall poor seed quality and reduced market grade and value. In this book chapter, we introduce the general aspects of PSS, its symptoms, causal agents, associated disease CLB, disease development and epidemiology. An overview of research on germplasm screening and genetic resistance are also presented and discussed. In future studies, all *Cercospora* species or other fungi that cause PSS and/or CLB need to be identified. Investigation of the genetics basis of pathogenicity and discovery of other useful genes using genomic approaches will aid in the development of new control strategies for the pathogens. Moreover, screening the soybean genome to identify molecular markers linked to PSS-resistance genes will be valuable for breeders in developing resistant cultivars, and will facilitate selection for PSS resistance in future breeding efforts.

Chapter 42

**SOMATIC AND GONADAL TISSUE
CRYOPRESERVATION: AN ALTERNATIVE TOOL
FOR THE GERMPLASM CONSERVATION
IN WILD MAMMALS**

***Alexsandra Fernandes Pereira*, Alexandre Rodrigues Silva,
Gabriela Liberalino Lima and Andréia Maria da Silva***

Laboratory of Animal Germplasm Conservation, Federal Rural University of
Semi-Arid, Mossoró, RN, Brazil

ABSTRACT

The tissue cryopreservation represents an interesting tool for the conservation of animal biodiversity. The establishment of tissue banks has been indicated as a practical approach to the preservation of species and, associated with other biotechniques, it could provide the rescue or multiplication of endangered species. In general, a large number of wild species have been having their gonadal and somatic tissue cryopreserved and for this purpose, the vitrification is the method routinely used. There is a diversity in cryobiological properties and requirements among cell types within tissues, presenting a challenge for its procedure. Nevertheless, even with those obstacles, studies have shown satisfactory results in many wild mammalian species. The gonadal tissue use involves the possibility for the reestablishment of endocrine functions of the testes and ovary allowing the preservation and posterior use of spermatozoa and/or spermatogonial stem cell and oocytes for other assisted techniques. Recent developments in the autografting and xenografting of testes and ovary clearly demonstrated the potential value of cryopreserving gonadal tissue. Already on the somatic tissue, skin samples have been widely utilized because of the possibility of sampling a large group of animals, without a dependency of limitations regarding gender or age. Moreover, this tissue can be obtained quite easily at using a simple methodology with a reduced cost. In this sense, this chapter highlights the importance of

applying tissue cryopreservation to wild mammals conservation at showing the most recent studies in this area and the perspectives for its use in conservative programs.

Keywords: assisted reproduction, biodiversity, conservation, resource banks

1. INTRODUCTION

In the global overview, where the species extinction is an increasing problem, the worldwide conservation is a major concern due the biodiversity role in supporting life on Earth (Lopes et al., 2016). In this context, the establishment of germplasm banks is of a great importance, ensuring a genetic source of gametes that could be used in Assisted Reproduction Techniques or ART programs (Norton, 2014). Moreover, the germplasm cryopreservation is an effective approach for conservation and recovery of genetic diversity of wild mammals because it is not limited by the reproductive life span or the location of the breeders (Liu et al., 2012).

Currently, the conventional method of the effective preservation of endangered animal species is the cell cryopreservation; nevertheless, the cell cryopreservation cannot save tissue cells at all periods. Thun, the tissue cryopreservation is an alternative methodology for conservation of genetic material by establishment of biological resource banks or cryobanking (León-Quinto et al., 2009), aiming still its application in other reproductive biotechnologies, as somatic cell nuclear transfer or SCNT (Guan et al., 2010) and intracytoplasmic sperm injection or ICSI (Campos-Junior et al., 2014).

These resource banks can be used so both for *in situ* and *ex situ* conservation. Some studies have reported success in establishment of the banks derived from ovarian (León-Quinto et al., 2009), testicular (Campos-Junior et al., 2014) and somatic (León-Quinto et al., 2009) tissues. In this sense, progress has been made with different methodologies in same species and for each tissue and this chapter aimed to show the theoretical and technical aspects involved and the peculiarities observed in each tissue and/or species.

2. THE TESTICULAR TISSUE

In mammals, the spermatogenesis is a continuous, strictly regulated process, where spermatogonia multiply and differentiate into spermatozoa (Russell et al., 1990). This regulation involves all the microenvironment around these cells, called niche, which gives support and produces signals that regulate both cell renewal and spermatogonial differentiation. Thus, protocols for the testicular tissue cryopreservation should promote the preservation not only of spermatogonia, but of the whole niche around them, the Sertoli cells, myoid cells, Leydig cells and other interstitial cells, preserving the communication among them (Ning et al., 2012).

The cryopreservation of testicular samples is a technique applicable to different wild mammals, allowing the recovery and storage of genetic potential from valuable males. It consists on a practical method to be used when other techniques, as semen cryopreservation, are not available or not applicable (Abrishami et al., 2010). As an example, when animals in

zoological collections die or are castrated, the reproductive potential contained in their testicular tissue is currently discarded. Thus, the possibility to salvage this material based in the cryopreservation research could represent a valuable addition to genome resource banking (Pukazhenthil et al., 2006). Moreover, the technique could be applied to individuals in any reproductive stage (León-Quinto et al., 2009), and not necessarily after testicular excision, since there is the possibility of testicular tissue recovery through appropriate biopsy techniques.

In most cases, the testicular tissue cryopreservation has been associated to the xenografting procedures (Kaneko et al., 2013; Pothana et al., 2015). During the xenotransplantation of fragments into immunodeficient mice, a functional communication between recipient brain and donor testis has been established. This interaction allows the progression of spermatogenesis and the further recovery of fertile sperm (Arregui et al., 2014). Nevertheless, the obtaining of sperm derived from fresh xenografted testis tissue is only reported in few wild species, as bison (*Bison bison*, Abbasi et al., 2011), white-tailed deer (*Odocoileus virginianus*, Abbasi et al., 2012), and collared peccary (*Pecari tajacu*, Campos-Junior et al., 2014). Already, the results of sperm obtaining after testis tissue cryopreservation is even more rare in wild species, being only reported for rhesus monkey (*Macaca mulatta*, Poels et al., 2012) and Indian spotted mouse deer (*Moschiola indica*, Pothana et al., 2015).

Due to the importance and great perspectives for its application in wild mammals, our goal was to list the current relevant research conducted on the cryopreservation of testicular tissue, addressing aspects as the tissue collection, preparation, cryopreservation and evaluations.

2.1. Tissue Source

The collection of testicular tissue can be conducted from both pre and post pubescent individuals, as well as from live or recently dead animals. The death of animals is one of the main reasons for the loss of genetic diversity of endangered species. Moreover, sperm cannot be collected from immature males and cryobanking of testicular tissue combined with testis xenografting is a potential option for their conservation (Pothana et al., 2015).

The testis development is unusual because several cell types as Sertoli, Leydig, and spermatogonial cells arise from bipotential precursors present in the precursor tissue, the genital ridge (Svingen & Koopman, 2013). In this sense, the pre pubertal period is characterized by diverse population changes in the seminiferous epithelium and formation of the tubular lumen (Assis Neto et al., 2003; Aponte et al., 2005), which drastically differs from the morphological and physiological features present in post pubertal individuals. In the testicle of pubertal animals, the seminiferous tubules development is complete, as well as the maturation of Sertoli cells, hematotesticular barrier and spermatogenesis (Svingen & Koopman, 2013).

In the rare studies conducted in wild animals, the testicle has been completely collected and processed for preservation after the animal death, or after castration procedures (Thuwanut et al., 2013; Pothana et al., 2015). To our knowledge, there is no report regarding the application of biopsy techniques for testicular tissue recovery and preservation in wild mammals; however, we emphasize that this is an interesting alternative to be used with conservative purposes.

2.2. Tissue Preparations

In general, a nutritive medium is necessary for recovering and washing the testicular tissue immediately after its removal of the animal. This medium largely varies among research groups. In a study conducted in various wild species (*Jungle cat*, *Felis chaus*, *Panthera leo*, *Panthera pardus*, *Rusa deer*, *Rusa timorensis*, *Muntiacus feae*, *Sumatran serows* and *Capricornis sumatraensis*), the testicular tissue was immediately collected after the death. Further, samples were washed in standard sterile saline (NSS) supplemented with 1% penicillin-streptomycin and this media was used for the transport to the laboratory (Thuwanut et al., 2013). In a similar trial conducted in marmoset monkey (*Callithrix jacchus*), testicular tissue was washed and transported in ice-cold using sterile Dulbecco's modified Eagle's medium (DMEM) (Schlatt et al., 2002), while the phosphate buffering saline (PBS) was used for Indian spotted mouse deer (Pothana et al., 2015).

Another factor that usually varies among researches consists on the fragment size that will be subjected to cryopreservation. Thus, each fragment of testicular tissue can be cut in 0.5–1.0 mm³ for marmoset monkeys (Schlatt et al., 2002), 3.0 mm³ in collared peccary (Borges et al., 2015c), 1.0–2.0 mm³ in the Indian spotted mouse deer (Pothana et al., 2015) and 2.7 mm³ for others wild animals (Thuwanut et al., 2013).

2.3. Cryopreservation Techniques and Evaluations

Freezing Protocols

The testicular tissue cryopreservation is a challenge, since many cell types are involved in its compartments (Hovatta, 2000). The spermatogonia, Sertoli cells and Leydig cells are rich in cytoplasm and therefore, they are highly vulnerable to freezing and thawing processes. These cells have a large amount of intracellular water, which increases the risk for the formation of intracytoplasmic ice crystals, leading to the destruction of organelles. Moreover, various other modifications may occur, as excessive cellular dehydration caused by osmotic shock after the formation of extracellular ice and cytoskeletal breakdown upon exposure to low temperatures (Woelders et al., 2004).

Thus, for initiate the cryopreservation, testicular tissue should be completely detached from the epididymides. After, fragments (0.5–0.3 cm³) can be cryopreserved by slow freezing, rapid freezing or vitrification, using media composed by buffering substances, cryoprotectant agents (CPAs), sugars and protein sources.

In marmoset monkeys, testicular tissue fragments were incubated in 1.5 mL Leibovitz-L15 medium supplemented with 1.5 M dimethyl sulfoxide (DMSO), 0.1 M sucrose and 1% human serum albumin (HSA) for 20 min. Then, it was stored in cryovials and subjected to a slow freezing protocol in which the cooling was conducted using a programmable freezer at –140°C. Samples were then plunged into liquid nitrogen (LN₂) and transferred to storage. Subsequently, the warming of the cryovials was at room temperature for 1 min plus 1 min in water bath at 37°C and CPAs were removed by descending gradient of DMSO (1.0, 0.5 and 0.0 M) (Schlatt et al., 2002). In addition, fragments of testicular tissue derived from Indian spotted mouse deer were exposed during 30 min to DMEM/F12 HEPES supplemented with 10% DMSO and 80% fetal bovine serum (FBS). Cryovials were stored in an isopropyl alcohol container and placed in –80°C freezer during 24 h, and then transferred to LN₂ for storage. After warming, fragments

were cultured in DMEM/F12 HEPES medium supplemented with 10% FBS, 100 IU/mL penicillin–streptomycin e 40 µg/mL gentamycin (Pothana et al., 2015).

Thuwanut et al. (2013), who preserved the testicular tissue from various species, described a fast freezing protocol. Initially, fragments were incubated in 0.5 mL freezing medium I composed of mTCM199 containing 25 mM HEPES, 10% FBS and 7.5% DMSO and 7.5% ethylene glycol, EG, at room temperature for 10 min. Then, fragments were incubated in a 0.5 mL freezing medium II containing mTCM199 supplemented with 0.5 M sucrose, 20% FBS, 15% DMSO and 15% EG, during 30 min at 4°C. Tissue was stored in pre-cooled (4°C) wall-side cryovials that were horizontally placed on a rack 4 cm above LN₂ vapor for 10 min and plunged into LN₂. Warming of the cryovials was conducted at room temperature for 10 min in solution of mTCM199, 20% FBS and 1.0 M sucrose.

A vitrification technique was described for freezing the Rhesus monkey testicular tissue (Poels et al., 2012). Samples were equilibrated during 10 min at 4°C in Leibovitz-L15 medium supplemented with 7.5% EG, 7.5% DMSO, 0.25 M sucrose and 25 mg/mL HAS. Then, a further incubation for 5 min at 4°C in Leibovitz-L15 medium with 15% EG, 15% DMSO, 0.5 M sucrose and 25 mg/mL HSA was conducted. Samples were finally plunged into LN₂, the straws were inserted into precooled cryotubes and stored for 24 h in LN₂. Fragments were further warmed at 35°C in a solution containing 1.0 M sucrose in Leibovitz L-15 with 25 mg/mL HAS, and finally transferred to baths of warming solutions with decreasing sucrose concentrations (0.5, 0.25, and 0 M).

Based on these statements, we can realize that different protocols have been described for the cryopreservation of testicular tissue of wild animals, and they seems to report variate results. However, this fact indicates that there is no ideal protocol for testicular tissue conservation, justifying the development of future studies in order to improve the protocols.

Addition of Cryoprotectant Agents

The addition of CPAs is an essential and crucial factor for the success of cryopreservation techniques (Mycock et al., 1995; Szein et al., 2001). The penetrant CPAs are small molecules that readily penetrate cell membranes, producing bonds among hydrogen ions with intracellular water molecules, reducing thereby the freezing temperature of the mixture, and preventing the formation of ice crystals (Szein et al., 2001). Several studies have examined the cryopreservation of testis cell suspensions or tissue fragments using penetrant CPAs, as glycerol, EG, DMSO and propanediol (Abrishami et al., 2010). The use of at 3.0 and 6.0 M concentrations was efficient for the testicular tissue vitrification in collared peccaries, promoting nuclear and epithelium conservation (Borges et al., 2015c). On the other hand, the DMSO has shown the most promising results for the testicular tissue preservation in marmoset monkeys (Schlatt et al., 2002) and Indian spotted mouse deer (Pothana et al., 2015). Furthermore, the DMSO with EG, has been successfully used in the cryopreservation of testicular tissue in several wild mammals (Thuwanut et al., 2013).

The non-penetrating CPAs are high molecular weight agents, which act by increasing the viscosity of the solution (e.g., polyvinyl alcohol) or by binding to the heads of the phospholipid groups (e.g., sucrose and trehalose), protecting cell membranes from the cold injuries (Santos et al., 2008). They remain in the extracellular medium, promoting cell dehydration and are used in conjunction with the penetrating CPAs. Among the non-penetrating CPAs, sucrose has been widely used for testicular tissue cryopreservation (Schlatt et al., 2002; Yamini et al., 2016).

Nevertheless, the metabolites from the degradation of the cell cryoprotectants can be toxic, which is a limiting factor for the successful use (Fahy, 2010).

Tissue Analysis

The immunochemistry for DNA analysis and the xenotransplantation for the evaluation of the proliferative activity are the main assessments currently used for cryopreserved testicular tissue (Pothana et al., 2015). Through histological analysis, slides stained in hematoxylin-eosin have been used in order to analyze the number of seminiferous tubules, epithelium quality and nucleus aspects (Milazzo et al., 2008; Borges et al., 2015c). In collared peccaries, a nuclear preservation with intact nucleolus and only few cell membrane detached from the epithelium of the seminiferous tubules was observed after the testicular tissue vitrification using EG (3.0 M or 6.0 M), besides a low number of cells presenting vacuoles (Figure 1) (Borges et al., 2015c).

Figure 1. Testicular tissue vitrification in collared peccaries using 3.0 M EG as CPAs. (A) Fresh testicular tissue. (B) vitrified testicular tissue. Scale bar: 200 μ m.

In vitro growth of cells derived from male gonads has been reported as an efficient tool for the evaluation and development of cryopreserved tissue (Lee et al., 2016; Yokonishi et al., 2014). To optimize the culture medium, the use of supplements as specific growth factors for different cell types, hormones, vitamins and lipids are needed (Valk et al., 2010). In domestic animals, *in vitro* culture as classical organ culture method and 3D printing has been used (Sato et al., 2011); nevertheless, in wild mammals, only the use of xenotransplantation is reported (Campos-Junior et al., 2014).

The xenotransplantation, considered as an *in vivo* culture, is currently used for the development of spermatogenesis using cryopreserved testicular tissue (Abrishami et al., 2010; Mota et al., 2012; Lee et al., 2016). Briefly, the xenotransplantation involves the grafting of small pieces (1–2 mm³) of testis parenchyma from one species under the skin or testicular capsule of an orchidectomised immunodeficient mouse. Unlike attempts to reproduce spermatogenesis under *in vitro* conditions, this technique has the advantage of maintaining the complex architecture of the testis (Pukazhenthil et al., 2006). In wild mammals, xenotransplantation was performed in ferret (Gourdon & Travis, 2012) bison (Abbasi et al., 2011), white-tailed deer (Abbasi et al., 2012) and collared peccary (Campos-Junior et al., 2014).

while for cryopreserved testis tissues, it was only reported for Rhesus monkey (Poels et al., 2012) and Indian spotted mouse deer (Pothana et al., 2015).

In collared peccary, fresh testis fragments from pre-pubertal individuals were successfully preserved under the skin of SCID mice with complete spermatogenesis being observed at 6 months after grafting. Additionally, when testis cells isolated from the same peccaries were xenografted, they were able to interact and *de novo* testis morphogenesis occurred, with complete spermatogenesis being observed only at 8 months after xenografting (Campos-Junior et al., 2014).

In the Indian spotted mouse deer, the testicular tissue fragment was submitted to xenotransplantation and xenografts were recovered after 24 weeks, showing advanced germ cells. The nuclear staining confirmed the proliferative status of spermatocytes, the increases in the tubular lumen diameters and indicated testicular maturation (Pothana et al., 2015).

2.4. Use of Testicular Tissue in the Conservation Programs

The testicular tissue cryopreservation is an interesting tool to be used in programs for the conservation of genetic variability. This technique has been improved in domestic animals, in which the production of viable sperm undergoing ICSI was possible, generating normal offspring (Kaneko et al., 2013). In wild mammals, however, there are only few studies describing the application of this technique. In general, the testicular tissue comes derived from dead animals; nevertheless, the biopsy collection can be an alternative to tissue collection.

Thus, the prospects for the technical improvement and its use in conservation programs are promising. In 2002, the Biological Resource Bank for Spain endangered wildlife was raised. This bank has stored cryopreserved testicular tissue derived from Iberian lynx (*Lynx pardinus*) using the CPAs as DMSO and glycerol (León-Quinto et al., 2009). Following this example, other biobanks can apply this technique for valuable genetic material conservation.

3. THE OVARIAN TISSUE

The success of ARTs applied for the conservation of genetic material derived from endangered females is limited. The main causes involve the low number of matured oocytes that can be obtained through hormonal stimulation or during *post-mortem* gamete rescue (Jewgenow et al., 2011; Tanpradit et al., 2015). To circumvent these obstacles, the storage of intragonadal gametes by ovarian tissue cryopreservation has been suggest, representing a potential strategy for the preservation of germ cells of young individuals that die before reaching sexual maturity or without offspring (León-Quinto et al., 2009). In this sense, genome storage centers around the world are stimulating the ovarian tissue collection and cryopreservation from many threatened and critically endangered animal species as a means of preserving genetic diversity (Paris et al., 2004).

Mammals have a large ovarian reserve of preantral follicles (PAFs) stored in the ovarian cortex, from which, a great pool of oocytes are enclosed in primordial follicles that represents about 90% of all ovarian follicle population (Santos et al., 2010). These follicles are more resistant to low temperatures once the oocyte at this stage of development has low metabolic

rate, absence of meiotic spindle, pellucid zone and cortical granules, and smaller amount of lipid droplets than matured oocytes (Hovatta, 2005). Therefore, female fertility preservation by ovarian tissue cryopreservation is a powerful strategy for species conservation (Tanpradit et al., 2015).

Some oocyte characteristics represent challenges to define a cryopreservation protocol for these cells. Immature germinal vesicle stage oocytes have not yet formed spindle, have no cortical granules and have high membrane permeability. Due to this, it has been suggested that germinal vesicle stage oocytes might be more resistant to chilling injury than metaphase II oocytes (Tucker et al., 1998). However, some authors reported spindle abnormalities after *in vitro* maturation of frozen oocytes at germinal vesicle (Boiso et al., 2002; Stachecki et al., 2004).

Since that most oocytes are located within primordial follicles in the ovarian cortex, obtaining a small fragment of cortical tissue potentially enables cryopreservation of large numbers of oocytes at germinal vesicle stage (Practice Committee of American Society for Reproductive Medicine, 2014). Consequently, cryopreserving the ovarian tissue avoids many limitations found in matured oocytes preservation, as the low number of matured oocytes available in the ovaries and the possible deleterious effects of its conservation under low temperatures (Santos et al., 2010). Besides, many studies are focusing on ovarian tissue preservation due its large application on ARTs in association with transplant, promising tools for ovarian function resumption (Faustino et al., 2011). Because of the characteristics of being relatively resistant and tolerant to ischemia due the relatively low metabolic rate, it is assumed that PAFs are the first to benefit from neo-vascularization after transplantation (Aerts et al., 2010).

3.1. Tissue Source and Preparation

The ovaries can be obtained from animals of any age, including fetuses, as well as immediately after death (Cleary et al., 2001). The major limitation of its use is the difficulty of preserving ovary tissue, considering the diversity of cell types and tissue components (Hovatta, 2005), that vary in size, distribution, and quantity and by many follicular development stages cells. It represents an obstacle to find an optimal permeability for CPAs (Lunardi et al., 2016).

Despite the obstacles, the cryopreservation process can be applied using ovarian fragments obtained from live animals by laparoscopy (baboons, *Papio anubis* – Lu et al., 2014; Rhesus monkeys – Ting et al., 2013), ovariectomy (lions, *Panthera leo* – Wiedemann et al., 2012) and after animal death (common wombats, *Vombatus ursinus* – Wolvekamp et al., 2001).

The size of ovarian tissue fragments also plays an important role in the success of the cryopreservation procedures. Commonly, small fragments (<1.0 cm) are used, especially when vitrification techniques are performed (Amorim et al., 2011), allowing the penetration of the vitrification solution into tissue. Moreover, the cryopreservation of the whole ovary has been reported successfully in some species, as wallabies (*Macropus rufogriseus*, Mattis et al., 2002), yellow toothed caviar (*Galea spixii spixii*, Praxedes et al., 2014) and marmoset monkeys (*Callithrix jacchus*, Motohashi & Ishibashi, 2016). For all these cases, after removal of ovarian samples, they are washed in a variety of media supplemented with protein source and antibiotics, before being exposed to cryopreservation solution.

3.2. Cryopreservation Techniques and Evaluations

The cryopreservation process involves the steps of exposure to CPA, chilling, storage, thawing or warming and cryoprotectant removal (Santos et al., 2008). The step of the CPA addition is crucial and indispensable for the success of the preservation and its presence is necessary for the cell survival (Mycock et al., 1995). Nevertheless, the metabolites produced from the degradation of these substances inside the cell might be toxic and it is a limiting point for the success of technique (Fahy, 2010).

Regarding the methods for ovarian tissue cryopreservation, the slow freezing and vitrification are described for this purpose. The slow freezing or conventional freezing protocol involves ovarian tissue exposure to low concentration of CPAs, followed by a step-by-step temperature lowering, according to the program's settings of programmed freezers (Filatov et al., 2016). Some studies revealed that this procedure led to some damages on ovarian stromal, granulosa and theca cells (Amorim et al., 2012), resulted from intracellular ice formation during freeze-thawing processes, which damages cells and your interactions (Tanpradit et al., 2015).

The chilling injury usually occurs between +15 and -5°C and causes changes in the lipid droplets, membranes, and microtubule of the mitotic or meiotic spindle of the oocytes (Aman & Parks, 1994; Martino et al., 1996). On the other hand, ice crystal formation, which occurs between -5 and -80°C, is considered the major source of cryoinjuries (Paynter, 2005). The ice crystal formation occurs due a high instability state caused by super cooling of intracellular water, and it is responsible by the mechanical rupture of cell plasmatic membrane (Zhmakin, 2008). The thawing process might cause it too, forming microcrystals as the result of ice recrystallization (Salle et al., 2002). Both injuries are very common in slow freezing protocols; however, it has been suggested that rapid cooling might prevent it (Wang et al., 2012).

In order to avoid damages caused by conventional freezing protocols, vitrification procedures have been used. It is considered a cheap method that can be performed under field conditions with no need for special equipment, making it a good alternative for use in various settings often encountered with wildlife mammals (Saragusty & Arav, 2011), including after animal death (Amorim et al., 2011). It avoids the development of ice crystals (Mukaida & Oka, 2012), promoting the formation of an amorphous glassy solid state (-20.000 to -40.000°C/min, Lin et al., 2008), using high cooling rates and CPA concentrations (Chung et al., 2013).

The efficiency of ovarian tissue vitrification has made possible the current establishment of female germplasm banking in donor programmes (Nagy et al., 2009). It is proposed that this procedure would be the most significant advance in cryobiology (Amorim et al., 2011) and, in the future, it is expected that vitrification becomes the most adequate method for the cryopreservation of any cell and tissue (Mukaida & Oka, 2012).

When vitrification is adopted, the Leidenfrost effect is a factor that can affect heat transfer, thus, resulting in low cooling rate (Sansinena et al., 2010). It occurs when the object is plunged into LN₂, as soon as it happens, the heat flow from the object to nitrogen resulting in strong nitrogen vaporization around the sample surface, that acts as an insulator, delaying heat transfer. To avoid this phenomenon, it has been proposed the slush nitrogen method (Santos et al., 2012), that consists of applying negative pressure, obtaining a solid/liquid nitrogen mixture (slush), that increases the cooling rate (Talevi et al., 2016). Nevertheless, this method has not been tested in wild animals yet.

Due the lack of basic information about the reproductive physiology of the majority of wild species, and the ignorance on oocyte osmotic tolerance or toxicity tests (Comizzoli et al. 2012), female gamete cryopreservation is not a well-established technique for these species (Andrabi & Maxwell, 2007). Once established, knowledge on cryopreservation of follicles *in situ* could be applied to endangered species allowing the maintenance and exchange of rare female genome. In this regard, the development of *in vitro* culture systems capable to promote complete growth of immaturated oocytes, present in ovarian tissue, has to be accomplished (Lopes et al., 2016). The use of oocytes enclosed in PAFs would provide the rescue of over than 95% of all ovarian follicle population (Silva et al., 2004). The possibility of *in vitro* culture and maturation of such oocytes would provide new knowledge about the mechanisms involved in the folliculogenesis of a given species, and also offers opportunities for its use in many others reproductive techniques (Comizzoli et al., 2010). Still, the required conditions for the complete *in vitro* development of PAFs are not established, in wild mammals, once data regarding follicular and oocyte growth are scarce (Figueiredo et al., 2008).

As an alternative, ovarian tissue transplantation has been reported as a promising way for obtaining viable oocytes for further exploration in ARTs. As the use of *in vivo* strategies to mature frozen-thawed ovarian tissue for animal conservation have been limited due immunological barriers from grafting ovarian tissue between individuals, xenotransplantation is a way to overtake these limitations (Paris et al., 2004). Many reports pointed ovarian tissue can survive, grow and mature after xenotransplantation into different species and sexes, presenting a practical tool for the study of *in vivo* follicular development (Meirow et al., 2016). It not only provides the possibility of access a source of gametes from ovarian tissue, but also acts as a tool to understand the mechanism of follicular development (Tahaei et al., 2015; Kikuchi et al., 2011).

Promising results were reported in many species, including the offspring obtained from Rhesus monkeys freshly autografted ovarian tissue (Lee et al., 2004), and many children derived from cryopreserved ovarian tissue autograft (Donnez et al., 2015; Jensen et al., 2015). Therefore, it is hypothesized that oocytes derived from such grafted ovarian tissue have the potential to give rise to live young (Paris et al., 2004), and be applied for several other wild ones.

3.3. Current Applications of Ovarian Tissue in Conservation Programs

Ovarian tissue cryobanks allow the storage of a large source of follicles from which many matured oocytes may be subsequently used in ARTs. Several research groups and centers are working to collect and to preserve a variety of biological material from threatened or endangered mammalian species (Andrabi & Maxwell, 2007). In this sense, some reports (Table 1) present encouraging results for this use as a tool for endangered species conservation.

With the purpose of forming a biological resource bank, Leon-Quinto et al. (2009) cryopreserved the ovaries from six Iberian lynx females, 24 to 72 h after animal death. Thus, the ovary was divided into three parts and cryopreserved by using slow freezing protocols adapted from domestic mammals. This work highlights the importance and role of tissue cryopreservation for germplasm storage from endangered animals.

Table 1. Cryopreservation of ovarian tissue in some wild mammals

Technique	Species	Main outcomes	Authors
Vitrification	<i>Papio anubis</i>	Autografting: follicle survival, growth and ovulation	Lu et al. (2014); Nyachio et al. (2013)

4. THE SOMATIC TISSUE

The cryopreservation of somatic tissue is an alternative source for the preservation of genetic material, aiming the conservation of animal biodiversity. The establishment of somatic sample banks has been indicated as a practical approach to the preservation of species and

associated with other reproductive biotechniques, as nuclear transfer (cloning), provides the restoration of endangered species (Loi et al., 2001; Folch et al., 2009).

In general, the cryopreservation of somatic samples has different applications beyond of the SCNT, including the preservation of the genetic material of the species. Thus, it can avoid the total loss of biodiversity in individuals who died prior to the reproductive stage, as well as allowing the study of the species by *in vitro* cell culture and basic research related to genetic, toxicology, among others (León-Quinto et al., 2009; 2011). Additionally, the cryo-preservation allows proper storage of samples, both during the transport to the laboratory as for a long time aiming the cryobank formation (Wong et al., 2012). In all cases, the use of conservation techniques as cooling, slow freezing and vitrification is required.

Different protocols have been employed and methodological adjustments, especially on the type and the concentration of the CPAs and technique type, are constantly being developed for wild species. Moreover, the methodologies applied for wild mammals are established in accordance with procedures used in domestic mammals.

Both somatic tissues as cells can be cryopreserved (León-Quinto et al., 2009; Machado et al., 2016); nevertheless, in situations where the habitat of animals of interest is difficult to access or far from *in vitro* culture laboratory, methods can be proposed for the conservation of somatic tissue before cell recovery (Silvestre et al., 2003). Additionally, use of tissue samples has also the advantages that can be cryopreserved without the need of a specialized laboratory, in situations where the procedures of *in vitro* culture are not yet established. Thus, an interesting step would be the establishment of the period and tissue storage conditions that do not influence the viability of cells recovered.

Therefore, we aimed here to approach the technical and theoretical aspects with emphasis in the source of somatic tissue and the recovery procedures, besides of the laboratory processing and the different freezing techniques and methods for its evaluation.

4.1. Tissue Sources

Somatic tissue samples have been widely used due the possibility of sampling a large group of animals. Moreover, it does not depend on the limitations of gender or age, allowing an unlimited number of samples and extrapolation of the cell characteristics of these animals for the entire population (Andrabi & Maxwell, 2007; León-Quinto et al., 2009). This is an interesting aspect, especially in the case of species from which is difficult to obtain gametes.

Nevertheless, the establishment of cryobanking requires the development of appropriate protocols and the suitable choice of the region or tissues to be collected from the animals (Cetinkaya & Arat, 2011). Moreover, this tissue should be obtained quite easily at using a simple methodology at low costs (Singh & Ma, 2014).

Skin Biopsy

In general, skin tissue fragments can be obtained by biopsies from live animals (Borges et al., 2015a,b) and/or during necropsies from dead individuals (Oh et al., 2008). In the latter situation, information on the cause and the *post-mortem* time are important for further procedures. Moreover, different solutions are described for the tissue collection as the phosphate buffer used for *P. tajacu* (Borges et al., 2015a,b) or a culture media used for *Ursus arctos* (Caamaño et al., 2008) and *Panthera tigris tigris* (Guan et al., 2010), both with

supplementations to ensure tissue viability during transport and/or procedures. In the latter work, somatic tissue derived from the skin were collected in DMEM supplemented with 100 U/mL ampicillin and 100 µg/mL streptomycin. Already in wild endangered Chilean native species (Tovar et al., 2008), biopsied skin, including dermal, epidermal and fat tissues were recovered in Earl Balanced Salt Solution (EBSS) plus antibiotic-antimycotic mixture.

In all situations (biopsies or necropsies), the region to be manipulated in the animal will be shaved and sanitized prior to collection. In general, skin fragments can be recovered of different regions, as auricular (*Bos gaurus*: Mahesh et al., 2012), abdominal (*Canis lupus*: Oh et al., 2008), scalp (*Cervus elaphus*; Berg et al., 2007) and fetal origin (*L. pardinus*; León-Quinto et al., 2014). In some species of difficult access, as *Hippocamelus biculcus* (Tovar et al., 2008) the darts can be used for to collect skin samples. For biopsies derived from the darts, a special system is used and it is fired to the area of the large muscle masses utilizing a projector powered by cartridge. Thus, a small sample is aseptically recovered from inside the dart, and destined to the following procedures.

Others Sources of Somatic Tissues

Due to the ease of harvesting for skin samples, few studies relate the conservation of other somatic tissues sources. An interesting example can be cited for *L. pardinus* (León-Quinto et al., 2009). In this study, the authors attempted to form a bank of somatic samples and recovered different somatic types, as muscle, oral mucosa, bone marrow, spine marrow and intestines, under the similar conditions used for skin samples. As a result, they obtained a total of 69 individuals (35 males and 34 females) from the somatic material collected. Thus, considering that in 2006 (period of experiment), the population of *L. pardinus* was about 170 individuals, a somatic bank reflected a very important fraction of the population biodiversity existing for the species.

4.2. Tissue Preparations

In the laboratory, all fragments can be washed through an aseptic procedure in order to ensure the viability of the samples. For that, various washing media can be employed. In general, biopsies should be washed in nutrient medium supplemented with antibiotics, buffers and/or protein sources. For *L. pardinus*, the authors described a medium consisting of DMEM supplemented with 25 mM HEPES, 100 U/mL penicillin, 0.1 mg/mL streptomycin and 1% fungizone (León-Quinto et al., 2014).

After washing, the determination of fragment size depends on the technique employed (Xia et al., 2013), but they usually measure around 1.0 mm³ (Song et al., 2007). Nevertheless, there are variations depending on the tissue availability (Tovar et al., 2008) and the cryopreservation type and materials used (Borges et al., 2015a,b). In *P. tajacu* and *Dasyprocta leporina* (Costa et al., 2015), for examples, samples were fragmented in 9.0 mm³ (3 x 3 x 1 mm), according to the vitrification protocol used.

4.3. Cryopreservation Techniques and Evaluations

After the obtainment of the tissue samples, these can be subjected to cooling (Tovar et al., 2008) and/or cryopreservation techniques (Table 2), as slow freezing (Caamaño et al., 2008; León-Quinto et al., 2009) and vitrification (Borges et al., 2015a,b; Costa et al., 2015). In general, the choice of method for tissue preservation depends on the required period and handling conditions.

The tissue samples can be firstly cooled in the presence or absence of nutrient medium over a relatively short-term, for example, for the transport of samples between geographically distant regions or intricate conditions. In the context, Tovar et al. (2008) verified the cooling conditions of tissue samples derived from different species for short-term at 4°C using chilled domestic cooler and EBSS as medium for conservation. These authors observed that skin samples derived from wild species of Chilean could be stored at 4°C for one week and still yield primary cultures with fibroblasts resulting in a 92% efficiency for the fragments conservation.

As another alternative, fragments could be stored for long periods in order to form biobanks. Both the methods (slow freezing or vitrification) consist on the exposure of tissue to CPAs, cooling storage, warming and removal of CPAs from tissue fragments (Silva et al., 2015). Although the methodologies currently applied for cell cryopreservation be routinely used and extrapolated for tissues, adaptations and establishment of protocols are necessary in order to adjust the specific requirements of the tissue (Zieger et al., 1996). This is more even complex because they contain different cell types that vary in volume and water permeability (Gandolfi et al., 2006).

For all processes, the use of penetrating and non-penetrating CPAs is necessary and different responses can be observed after their use. In *Sus scrofa*, for example, frozen skin fragments without the presence of CPAs showed culturable cells (Zhang et al., 2012). Already in *P. tajacu*, Borges et al. (2015a,b) obtained viable cells derived from tissues vitrified with DMSO, EG and sucrose. In *U. arctos*, viable cells were obtained from tissues frozen with DMSO and vitrified with the association of DMSO and EG (Caamaño et al., 2008). In this sense, the presence of CPAs and its choice are important factors for the efficiency of cryopreservation (Ehrlich et al., 2015). Additionally, during the tissue exposure to CPA followed of cooling, the main differences between the types of cryopreservation, slow freezing and vitrification are highlighted.

Briefly, the slow freezing protocol used for somatic tissue (Caamaño et al., 2008) consists in the following steps. First, the incubation of small fragments in 1.0 mL of freezing medium (DMEM supplemented with 10% DMSO and 10% FBS) using cryovials. Then, the cooling using the system Mr. Frosty (box containing isopropanol) at -80°C and overnight. Followed by the storage in LN₂. Finally, the warming of the cryovials at 38°C for 2 min, removal of freezing medium and mix with 1.0 mL of DMEM plus 10% FBS.

For the vitrification method, as occurs for other tissues, there are some variations (Carvalho et al., 2011, 2012). Two different systems have already been employed for wild animals. The first consists on a conventional method that uses cryovials and that was applied for *U. arctos* (Caamaño et al., 2008), *P. tajacu* (Borges et al., 2015a,b) and *D. leporina* (Costa et al., 2015). The other method consists on the solid-surface vitrification (SSV) procedure described for *P. tajacu* (Borges et al., 2015a,b) and *D. leporina* (Costa et al., 2015).

Table 2. Cryopreservation of somatic tissue in some wild mammals

Species	Tissue source	Cryopreservation				Authors
		Technique	Cryoprotectors	Evaluation ^a	Destination	
<i>U. arctos</i>	Skin biopsy	Freezing	20% DMSO, 20% EG	<i>In vitro</i> culture	Cryobanking	Caamaño et al. (2008)
<i>L. pardinus</i>	Skin biopsy, muscle, oral mucosa, bone marrow, spine marrow, intestines	Freezing	NI	NI	Cryobanking	Léon-Quinto et al. (2009)
<i>S. scrofa</i>	Skin biopsy	Freezing	None	<i>In vitro</i> culture and production of clone embryos	SCNT	Zhang et al. (2012)
<i>U. arctos</i>	Skin biopsy	Vitrification	10% DMSO, 10% FBS	<i>In vitro</i> culture	Cryobanking	Caamaño et al. (2008)
<i>P. tajacu</i>	Skin biopsy	Vitrification	20% DMSO, 20% EG, 0.25 M sucrose, 10% FBS	Histological analysis and <i>in vitro</i> culture	Cryobanking	Borges et al. (2015a,b)
<i>D. leporina</i>	Skin biopsy	Vitrification	20% DMSO, 20%, 0.25 M sucrose, 10% FBS	Histological analysis	Cryobanking	Costa et al. (2015)

Abbreviations: DMSO: dimethyl sulfoxide, EG: ethylene glycol, FBS: fetal bovine serum, SCNT: somatic cell nuclear transfer; NI: not informed.

^aMore information about the evaluation see reference.

In the protocol used for conventional vitrification, fragments are initially incubated in 1.0 mL DMEM as vitrification medium supplemented with 20% DMSO, 20% EG and 20% FBS and placed in cryovials. Samples were equilibrated for 10 min at room temperature, and finally plunged and stored in LN₂. The posterior warming of the cryovials was conducted at 38°C for 2 min, followed by the removal of vitrification medium and mix with 1.0 mL DMEM plus 10% FBS.

Regarding the SSV technique (Borges et al., 2015a,b), fragments are exposure to DMEM as vitrification medium supplemented with 20% DMSO, 20% EG, 0.25 M sucrose and 10% FBS) in Petri dishes for 5 min. The excess of CPAs is removed, and the samples are deposited on a metal cubic surface partially placed in LN₂. Then, samples are transferred to cryovials and immersed directly in LN₂. Finally, warming of the cryovials is conducted at 37°C for 1 min and the vitrification medium is removed through washings in DMEM supplemented sucrose at 0.50, 0.25 M and no sucrose for 5 min.

In general, the somatic tissue cryopreservation is a strategy for genetic conservation of wild animals (Benkeddache et al., 2012). For this purpose, the vitrification strategies are currently considered more efficient than conventional cryopreservation in domestic species (Brockbank et al., 2010). Although the development of vitrification has greatly simplified cryopreservation procedures, the protocols already established for other types of tissue may not be ideal to be applied for the tissue of the target species (Da-Croce et al., 2013). In the vitrification, the solution is rapidly cooled and transformed into a glassy (Amorim et al., 2011). The choice for the vitrification is due to the time consumed to perform the technique, the more economical and practicality to be performed in any laboratory (Ting et al., 2013). Moreover, for optimum conditions, a small volume of the vitrification solution is required to be in contact to the tissue cryopreserved. Thus, the SSV provides the use of a small amount of a cryoprotectant consisting of direct exposure of the tissue to a solid surface pre cooled (Carvalho et al., 2011).

In a previous study, we demonstrated that the SSV method was more able to preserve somatic tissue of *P. tajacu* (Borges et al., 2015a,b) and *D. leporina* (Costa et al., 2015) than the conventional vitrification. In these works, we showed that the SSV was the most appropriate method for the vitrification of somatic tissue and the recovery of viable somatic cells that could be destined to cloning.

On the other hand, a comparative study of two systems, freezing and conventional vitrification, was conducted in *U. arctos* skin biopsies (Caamaño et al., 2008). The authors observed that skin fragments could be preserved for long term, allowing fibroblasts to proliferate in culture. The vitrification led to poorer cell proliferation and more days to reach 70-80% confluence than freezing (19.2 versus 1.25 days). Moreover, the authors affirmed that skin vitrification needs further studies and refinement prior to its use on the field. Additionally, the vitrification has facilities as use only cryovials, vitrification solution and a small nitrogen tank.

As a criteria for the successful preservation of somatic tissue samples, the use of *in vitro* culture derived from samples is an essential tool for the identifying the cryopreservation damages. Thus, tissues fragments, after primary culture, can promote the detachment of the cells, as fibroblasts (Caamaño et al., 2008; León-Quinto et al., 2009; Borges et al., 2015b). All these cells can be assessed for quality, viability, proliferation and functional activity of the cultured cells. Additionally, the isolation of proliferating cells derived from cryopreserved tissues and the culture are essential analyzes for the establishment of the cryobanking (Léon-

Quinto et al., 2009), particularly for cloning purposes, which they can be used as karyoplasts that is nucleus donor.

Finally, some of cryopreservation artifacts can be observed by histological techniques. In general, the histological evaluation using hematoxylin-eosin provides a basic requirement for knowledge of the structures that were affected or maintained morphologically normal during cryopreservation. It enables the visualization of the tissue as both a whole as the analysis of their constituents, epidermis and dermis (Borges et al., 2015a). Other more specific techniques, as protein argyrophil related to nucleolar organizer regions allow for the recognition of cell proliferative activity (Cresta & Alves, 2007).

4.4. Use of Somatic Tissue in the Conservation Programs

Most somatic tissue banks are established from the skin of wild animals. In general, it is known that the ease of collection of the material and advances in cloning area allowed increasingly proper storage of somatic tissues. In this sense, several cases illustrate the importance of somatic cryobanking in wild mammals. Moreover, the same examples can be cited with the use of somatic cells.

In 2009, León-Quinto et al. established various biologic resource banks as a supporting tool for reproduction and conservation of *L. pardinus*. This species is considered the most endangered felid in the world, being confined in southern Spain and Sierra Morena (Simon et al., 2012). Thus, León-Quinto et al. showed that the somatic samples savage reflected on a very important fraction of the population biodiversity which will allow the development of a wide variety of works that can be easily extrapolated to the majority of the population. A total of 7 males, 6 females and 69 different individuals were collected for testicular, ovarian and somatic tissues, respectively (León-Quinto et al., 2009).

In 2010, Guan et al. established a fibroblast cell line derived from bengal tiger (*P. tigris tigris*). The tiger is warranted the highest level of protection by the Convention on International Trade in Endangered Species of Wild Fauna and Flora and, in 1989, the Chinese government brought *P. tigris tigris* into first category of National Protected Animal breed (Guan et al., 2010). Thun, in this study, the authors showed that also somatic samples can be cryopreserved and maintained in culture.

An interesting example of importance of somatic banks and cloning use can be evidenced with the study of Folch et al. (2009). The authors produced the first clone of *Capra pyrenaica pyrenaica*, an animal derived from as extinct caprine subspecies. Thus, the karyoplast used consisted on fibroblast derived from skin biopsies, obtained and cryopreserved in 1999 from the last living female, that died in 2000; the cytoplasm were matured oocytes derived from domestic goats. Thus, in 2009, one morphologically normal bucardo was produced. Unfortunately, newborn died some after birth. This study was the first using an extinct animal. Other previous works using cytoplasm of domestic animals with wild karyoplast resulting on live offspring were demonstrated for *B. gaurus* (Lanza et al., 2000) and *Ovis orientalis musimon* (Loi et al., 2001).

Finally, the somatic banks also can be employed for the production of induced cells to pluripotency (iPS or induced pluripotent stem). These cells can be obtained from fibroblasts using a culture system of defined factors (Takahashi & Yamanaka, 2006). In *Panthera uncial* (Verma et al., 2012) and *Mandrillus leucophaeus* (Ben-Nun et al., 2011), somatic cells already

were induced to pluripotency. The use of this tool would be interesting to allow an alternative way to produce gametes in endangered wild mammals.

5. GENERAL CONSIDERATIONS

The biodiversity conservation by tissue cryopreservation is a promising tool with different purposes, and can be applied both for the multiplication of a species as to a basic investigative study. In general, with regards to the conservation programs, there is a variation according to the species and the tissue; nevertheless, clearly there was progress in wild felids, especially for the Iberian lynx. Finally, improvements are still needed as the practical establishment of biological recourse banks in various species and their application in reproductive techniques.

BIOGRAPHICAL SKETCH

Name: Alexsandra Fernandes Pereira

Affiliation: Laboratory of Animal Germplasm Conservation, Federal Rural University of Semi-Arid – UFERSA

Education: Graduate in Chemistry, Doctor in Veterinary Sciences

Research and Professional Experience: Adjunct Professor of UFERSA, Member of the Brazilian Society of Embryo Transfer

Professional Appointments: Expertise in studying the assisted techniques applied to the animal conservation and reproduction (*in vitro* culture, parthenogenesis, *in vitro* fertilization and somatic cell nuclear transfer

Publications Last 3 Years:

ABSTRACT

We sequenced mitochondrial genes (*COI*, *COII*, *Cyt-b*) of accepted Latin America tapir species (*Tapirus pinchaque*, *T. terrestris* and *T. bairdii*) as well as an alleged new species, *T. kabomani*.

The mountain tapir (*T. pinchaque*) is a relatively rare large mammal species. Some population censuses indicate that no more than 2,000 mountain tapirs are left in the wilderness areas of Colombia, Ecuador and Peru. Our results showed that the gene diversity

* Corresponding Author's Email: mruizgar@yahoo.es, mruiz@javeriana.edu.co.

levels are medium to low with respect to other mammals sequenced for the same or similar genes. However, these gene diversity levels are not impoverished, which means that the genetic situation of this species is not as critical as its population censuses suggest. It will be crucial to determine the gene diversity levels in certain populations not included in the current work (the eastern and, possibly, western Andean Cordilleras in Colombia as well as the Tabaconas Namballe National Sanctuary in Peru), because they are probably the smallest populations of this species. On the other hand, the lowland tapir (*T. terrestris*), the species with the largest geographical distribution in Latin America, showed the highest gene diversity levels of all the other tapir species studied. Additionally, the genetic structure of *T. terrestris* is clearly more robust than that of *T. pinchaque*. Different geographic populations of both species showed different demographic trends throughout time. Our results including five samples of *T. kabomani* showed this taxon to be a haplogroup within *T. terrestris*, reducing the likelihood of *T. kabomani* being a new full species. Finally, we also analyzed the influence of diverse Pleistocene climatic changes on the mitochondrial haplotype diversification of *T. terrestris* and *T. pinchaque*. The Pleistocene Refugia and the Recent Lake hypotheses probably played integral roles in the evolutionary history of *T. terrestris*. In contrast, the Pleistocene Refugia hypothesis involving the Andes, which probably played an important part in the genetic diversification of other mammals, did not have a significant impact on *T. pinchaque*.

Keywords: mitochondrial genes (*COI*, *COII* and *Cyt-b*), *Tapirus*, *T. pinchaque*, *T. terrestris*, *T. bairdii*, “*T. kabomani*,” conservation genetics, speciation, pleistocene biodiversity hypotheses

INTRODUCTION

Large mammals are often considered umbrella or emblematic species whose presence may greatly affect community structure (Meffe and Carrol, 1997). In general, the extraction of large vertebrates, especially those at the top of the trophic chain, can provoke strong extinction waves in complex natural systems (Pimm, 1991). These species can be considered as key to overall community structure because they live sympatrically with many other species. For example, East (1981) showed that the preservation of viable populations of the African wild dog (*Lycaon pictus*) and the cheetah (*Acinonyx jubatus*), due to their large hunting territories, helped to preserve the communities of other large African mammals.

In Latin America, three wild large perissodactyla species have been traditionally accepted: the Baird or Central America tapir (*Tapirus bairdii*), the mountain tapir (*T. pinchaque*) and the lowland or Brazilian tapir (*T. terrestris*).

The fossil evolution of the Tapiridae is old and very interesting. Perissodactyla is a very old group of mammals that arose around 60 Million years ago (MYA). In the fossil record, there are representative specimens from five main superfamilies (Tapiroidea, Rhinoceroidea, Chalicotheroidea, Equoidea and Brontotheroidea) and 14 different families (Savage and Long, 1986; Holbrook, 1999). The order reached its maximum diversity peak during the Eocene and then declined from 14 to 4 families during the upper Oligocene (Radinsky, 1969; Froehlich, 1999; MacFadden, 1992; Metais et al., 2006). The Tapiridae family (Gray 1821) is currently composed of one unique genus, *Tapirus* (Brisson 1762). Colbert (2005) defined the Tapiridae family as the clade conformed by the most recent common ancestor of *Protapirus*. The oldest record of *Tapirus* comes from the European Oligocene (33-37 MYA), where the fossil remains

are found until the Pleistocene (McKenna and Bell, 1997). In North America, the *Tapirus* records indicate that they were present in the Middle Miocene through the present (Hulbert, 1995), whereas for Asia the records indicate that *Tapirus* has been in existence since the Lower Miocene (Deng, 2006). Currently, additional to the three quoted Latin American tapir species, there is a fourth species in Southern Eastern Asia, the Malayan tapir (*T. indicus*). Two of these species are exclusively distributed in South America and they are the subject of this work, from a genetics point of view. The mountain tapir (*T. pinchaque*) has a unique and critical role because it is an indispensable seed disperser in the Andean mountains (Colombia, Ecuador, Northern Peru) but its conservation status is in jeopardy because of its relatively low numbers (less than 2,500 individuals; Cavellier et al., 2010). Additionally, this is an umbrella species with an average territory size per tapir of 880 ha (Downer, 1996). This is a substantially large home range. Downer's work in the Sangay National Park suggested that a minimum of 1,000 mountain tapirs were needed to ensure a reproductively viable population. Such a population would need at least 293,500 ha. The necessary protection of this area would positively benefit many other sympatric animal species, like the Andean bear, puma, and various deer species (Downer, 1996). Indeed, the cloud forests of the Andean region, where the mountain tapir lives, contain some of the greatest organismic diversity on Earth (Brehm et al., 2005; Krömer et al., 2005), with a noteworthy number of endemic species (Kessler, 2002). However, about 90 % of the mountain Andean forests have been deforested (Henderson et al., 1991) and a great proportion of páramos has been transformed via burns into extensive ranchlands and croplands (potatoes) (Verweij, 1995). Additionally, around 83 % of Colombia's mountain forests have been highly affected by human activity (Cavellier and Etter, 1995). Besides ranching and agriculture, the mountain tapir is also highly threatened by poaching and illegal trade of its body parts (Downer, 2003). In Andean areas, the introduction of livestock has also spread new diseases and attracted more potential predators of the mountain tapir.

The lowland tapir has a wide geographical distribution across a great part of South America. From an ecological perspective, the lowland tapir is considered the "architect" of their Neotropical habitats because it is a very efficient disperser and seed predator (Wallace et al., 2010). Cabrera (1961) considered four morphological and geographical subspecies of *T. terrestris*: *T. t. colombianus*, *T. t. terrestris*, *T. t. aenigmaticus*, and *T. t. spegazzinni*. *T. t. colombianus* (Hershkovitz 1954; Type locality: El Salado, between Valencia and Pueblo Bello on the eastern slope of the Sierra Nevada de Santa Marta, in Magdalena, Colombia) inhabits Northern Colombia and around Maracaibo Lake in Venezuela. *T. t. terrestris* (Linnaeus 1758; Type locality: Pernambuco, Brazil) lives in Venezuela, Guyana, Suriname, French Guyana, with its major fraction in Brazil (including Amazonas) up to the Misiones within Argentina. *T. t. aenigmaticus* (Gray 1872; Type locality: Macas, Eastern Ecuador) is distributed in Southeastern Colombia, Eastern Ecuador and Northern/Eastern Peru (Amazonian area). *T. t. spegazzinni* (Ameghino 1909; Type locality: Rio Pescado, Orán, Salta, Argentina) is distributed in Southeastern Brazil and Mato Grosso, Paraguay, Eastern Bolivia and Northwestern Argentina.

Recently, Cozzuol et al., (2013) claimed the existence of a new tapir species ("*T. kabomani*") in South America based on a comparison of mitochondrial Cytochrome-b (*Cyt-b*) gene sequences of four Amazon tapir individuals (two Brazilian animals sampled by these authors and two Colombian specimens sampled by the first author of the present study, M. R-G) to the 45 *Cyt-b* gene sequences published by Thoisy et al., (2010). They also enclosed the results of two additional mitochondrial genes (mitochondrial Cytochrome Oxidase subunit I,

COI, and subunit II, *COII*) for six *T. terrestris*, one *T. pinchaque* and three individuals of the alleged new species “*T. kabomani*.” They concluded that the three mitochondrial genes supported “*T. kabomani*” as a full species. Voss et al., (2014), however, questioned the validity of “*T. kabomani*” as a different species from *T. terrestris*.

The current work provides some insight about the genetic structure and heterogeneity, demographic evolution, spatial structure, biological conservation, and systematics of the Latin American tapirs. Moreover, this work also explores the influence of the Pleistocene period on the Latin American tapirs. And, all of these insights are based on the analysis and study of mitochondrial genes *Cyt-b*, *COI*, and *COII*. These new data should be helpful in validating or rejecting the claim of a new species, “*T. kabomani*”.

MATERIALS AND METHODS

Two sets of data were used in this study. The first set consisted of 93 Latin American tapir individuals analyzed for three specific concatenated mitochondrial genes (*Cyt-b* + *COI* + *COII*). They were the same genes analyzed by Cozzuol et al. (2013) and whose mitochondrial sequences are accessible in GenBank for the two Brazilian specimens they classified as an alleged new species “*T. kabomani*.” Breaking the first group down by taxa, it had 46 *T. pinchaque*, 29 *T. terrestris*, 13 *T. bairdii*, and 5 *T. kabomani*. *T. pinchaque* was constituted by 26 from Ecuador representing three populations, Northern Ecuador, Sangay National Park and Podocarpus National Park, and the remainder of the 46 (20) was from Colombia representing three populations: Los Nevados National Park, Tolima and Purace National Park.

Another 29 of the first set were *T. terrestris*. Five of these individuals were from Ecuador, four were from Colombia, seven from Peru, three from Bolivia, three from Brazil, three from Surinam, and one was from Argentina. Three animals of the 29 were from American zoos in Cincinnati, Milwaukee and Columbus. Another 13 of the 93 were *T. bairdii*. Nine of these animals were from Panama, three were from Costa Rica and one was from Colombia. Five of the 93 were *T. kabomani*- including the two Brazilian specimens of Cozzuol et al., (2013). We detected three additional specimens with mitochondrial haplotypes of the alleged *T. kabomani*. There were from 1) San Martín de Amacayacu along the Amazon River in Colombia, 2) the Mazan River which is a tributary of the Napo River, in the Peruvian Amazon, and 3) near Tena along the upper Napo River in the Ecuadorian Amazon.

However, at least, two of these animals (the Colombian and the Ecuadorian ones) presented typical morphotypes of *T. terrestris*, although they showed “*T. kabomani*” haplotypes (see Figure 1). The Peruvian sample consisted of skin obtained from hunters and we could not determine the morphotype of the specimen.

The second set of individuals contained 141 *T. terrestris*, sequenced at the *Cyt-b* gene. Forty-one of these came from different regions of Colombia. Of these, 1 was from Bajo Sinú-Tierra Alta, (Córdoba Department), 2 were from Mesay River (Caquetá Department), and another was from Fondo Canaima, (Vichada Department). Of the 41, 18 were also from Leticia to San Juan de Atacuarí (Amazonas Department), 7 from the Eastern Colombian Llanos (Meta Department), 3 from Pto. Inirida (Guania Department), 3 from Palomino River-Sierra Nevada de Santa Marta and 6 from the Antioquia Department. Five of the 141 were from Venezuela (El Zulia, Maracaibo). Eleven of the 141 were from French Guiana (Carnopi River). Seven

animals were from Ecuador (4 from Limoncocha, Sucumbios and 3 from Coca, Sucumbios). Thirty animals were from Peru [(one from Arica (Curaray River), 2 from Napo River (Nueva Vida and Mazán), 7 from Nanay River, one from Requena (Ucayali River), one from Breña (Canal del Puhinauva-Ucayali River), 4 from Pucallpa (Ucayali River), and 15 from Pto. Maldonado (Madre de Dios River)]. Eleven animals were from Bolivia (9 from Mamoré River, one from Chimoré River and one from Villa Bella at the Beni River). Twenty four animals were from Brazil [2 from Yavarí River, 12 from Tabatinga, 2 from Negro River, 2 from Santarém (Pará state) and 6 from the Amazon's mouth (Pará state)]. One animal was from Paraguay (from Hernandarias). And, 4 animals were from Argentina (the Yungas area in Salta-Jujuy). Additionally, one animal was from the Barcelona Zoo (Spain) and 5 animals were from US zoos. One animal of unknown origin was also analyzed.

Figure 1. An individual with morphotype of *Tapirus terrestris* but with “*T. kaboman*” mitochondrial haplotype from San Martín de Amacayacu, Amazon River, Colombian Amazon (A); An individual with morphotype of *Tapirus terrestris* but with “*T. kaboman*” mitochondrial haplotype from near to Tena, upper Napo River, Ecuadorian Amazon (B).

Molecular Procedures

DNA from teeth, bones, muscle, and skins, were obtained with the phenol-chloroform procedure (Sambrook et al., 1989), whereas DNA samples from hair and blood were obtained with 10% Chelex® 100 resin (Walsh et al., 1991). Amplifications for *Cyt-b* gene were achieved using primers L7 (5' ACC AAT GAC ATG AAA AAT CAT CGT T 3') and H6 (5' TCT CCA TTT CTG GTT TAC AAG AC 3'), that had been designed for perissodactyles (Tougard et al., 2001). The PCR reactions were performed in a 50- μ l volume, including 10 μ l of 10x Buffer, 7 μ l of 3 mM MgCl₂, 2 μ l of 10 mM dNTPs (dNTP Mix Promega), 4 μ l (15 pmol) of each primer, one unit of Taq DNA polymerase (genTaq polimerasa), 2 μ l of DNA from blood, skin or muscle tissue (50-200 ng/ μ l) or 4-10 μ l of DNA from hair and teeth (6-35 ng/ μ l) and a variable quantity of ddH₂O. PCR reactions were carried out in a Geneamp PCR system 9600 (Perkin Elmer) and in an iCycler™ BioRad thermocycler. We used the following temperatures: 94 °C for 5 minutes, 35 cycles of 50 s at 94 °C, 50 s at 53 °C and 1.5 minutes at 72 °C and a final extension time for 10 minutes at 72 °C. For the *COI* and *COII* genes, the amplification conditions followed Ashley et al., (1996) and Hebert (2003, 2004). All amplifications, including positive and negative controls, were checked in 2 % agarose gels, employing the molecular weight marker ϕ X174 DNA digested with *Hind* III, *Hinf* I and HyperLadder IV. The gels were visualized in a Hoefer UV Transilluminator. Those samples that amplified were purified using membrane-binding spin columns (Qiagen). The double-stranded DNA was directly sequenced in a 377A (ABI) automated DNA sequencer. The samples were sequenced in both directions and all the samples were repeated to ensure sequence accuracy.

Data Analyses

Genetic Diversity, Linkage and Heterogeneity Analyses

The sequences were edited and aligned with BioEdit Sequence Alignment Editor (Hall, 2004) and DNA Alignment (Fluxus Technology Ltd).

We used the following statistics to determine the genetic diversity at the three concatenated mitochondrial genes for *T. terrestris*, *T. pinchaque*, *T. bairdii* and the alleged "*T. kabomani*": the number of polymorphic sites (S), the number of haplotypes (H), the haplotypic diversity (H_d), the nucleotide diversity (π), the average number of nucleotide differences (k) and the θ statistic by sequence.

The possible linkage disequilibrium within the *Cyt-b* gene for *T. terrestris* was evaluated by two different statistics. We obtained the average value of R^2 for all the comparison pairs among nucleotide sites (ZnS) (Kelly, 1997) as well as among the adjacent polymorphic nucleotide sites (Za), and ZZ (Rozas et al., 2001). This is equal to $Za - ZnS$, using the software DNAsp 5.10 (Librado and Rozas, 2009).

Different tests were carried out to measure genetic heterogeneity, and possible gene flow estimates, among the four Latin American tapir taxa studied. These tests were those of Hudson et al., (1992a,b) (H_{ST} , K_{ST} , K_{ST}^* , Z , Z^*), Hudson (2000)'s Snn test and the chi-square test on the haplotypic frequencies with permutation tests using 10,000 replicates. We also estimated the G_{ST} statistic from the haplotypic frequencies and the γ_{ST} , N_{ST} and F_{ST} statistics (Hudson et al., 1992a) from the nucleotide sequences.

We carried out two different AMOVA analyses at the *Cyt-b* gene for *T. terrestris* to determine if the gene diversity within this species was distributed in different hierarchical geographical levels (Excoffier et al., 1992). The first analysis was carried out taking into account the six haplogroups found in the phylogenetic analysis clustered in three main population sets: northern, Amazonian, and southern. Thus, this analysis was applied to the overall geographical *T. terrestris* range analyzed. The second analysis was completed taking into account six different geographical areas within the Amazon basin: 1-Northwestern Amazon in Colombia and Brazil, 2- Central and Eastern Brazilian Amazon, 3-Napo River and a tributary in Peru and Ecuador, 4- Ucayali River in Peru, 5-Madre de Dios River in Peru and 6- Mamore River and a tributary in Bolivia. These six geographical areas were clustered into two main groups: northern Amazon (the first three areas) and southern Amazon (the last three areas). This analysis was carried out to determine the gene diversity structure in the Amazon region. The fixation indices of Wright (1951) were estimated: Φ_{sc} (variation of populations within the groups), Φ_{ct} (variation among groups) and Φ_{st} (variation among individuals). These analyses were carried out by means of the software ARLEQUIN 3.0 (Excoffier et al., 2005).

Phylogenetic Analyses

The Modeltest (Posada and Crandall, 1998) and the Mega 5.1 software (Tamura et al., 2011) were applied to determine the best evolutionary nucleotide model for the analyzed concatenated gene sequences for all the *Tapirus* taxa studied.

To determine if *T. pinchaque* or *T. terrestris*, contained a more conspicuous genetic structure, we used a consensus maximum parsimony (MP) tree for the three concatenated mitochondrial genes. We also obtained a maximum likelihood (ML) tree to determine how many significant clades were within *T. terrestris*, at the *Cyt-b* gene. In this analysis, 80 *T. terrestris* haplotypes were considered (including two haplotypes later classified as “*T. kabomani*”). To carry out this task, we tested the hypothesis that the *T. terrestris* sequences fall into one to 10 different groups. These classifications were contrasted with the ML tree. For this, we performed parametric bootstrapping and a posteriori significance test with the Swofford-Olsen-Waddell-Hillis test (SOWH; Huelsenbeck and Bull, 1996; Swofford et al., 1996). The 10 hypotheses were used as a model tree for parameter estimation and for generating 100 replicate data sets in the software Seq-Gen 1.2.5 (Rambaut and Grassly, 1997) which presented a uniform base composition. Goldman et al., (2000) demonstrated that this procedure can increase power in rejecting the null hypothesis and is better than typical nonparametric tests for comparisons of a posteriori hypotheses. The same was performed with the Shimodaira and Hasegawa (1999) test (a nonparametric SH test).

We conducted two additional phylogenetic trees. One was a ML tree with the 93 tapirs sequenced at the three concatenated mitochondrial genes to determine the relationship of the five “*T. kabomani*” with regard to the other tapir taxa. The second was an ML tree with some animals only sequenced at the *COI* gene since this gene is used as a barcode to discriminate different species (Herbert et al., 2003, 2004). Similarly, we estimated the Kimura 2P genetic distance (Kimura, 1980), for the three mitochondrial genes, among all the Neotropical *Tapirus* taxa because this genetic distance is a standard measurement for barcoding tasks (Hebert et al., 2003, 2004).

Possible divergence times were obtained using a Median Joining Network (MJN) (Bandelt et al., 1999). These were applied to all the haplotypes of the three concatenated mitochondrial

genes for all the tapir taxa considered as well as to the *T. terrestris* haplotypes at the *Cyt-b* gene. These were constructed with Network 4.6 software (Fluxus Technology Ltd). The ρ statistic (Morral et al., 1994) was estimated and transformed into years. The standard deviation of ρ was also calculated (Saillard et al., 2000), which is unbiased and highly independent of past demographic events. Thoisie et al., (2010) used two different mutation rates: 5.6×10^{-3} and 2.5×10^{-2} substitutions/site/million years respectively. Relative to our work with the genus *Tapirus*, the first rate translated into around one mutation each 537,634 years. The second rate was equal to about one mutation each 120,482 years. This last mutation rate agrees quite well with that reported by Nabholz et al., (2008, 2009) for mammals at the *Cyt-b* gene. We employed an intermediate value of 1.5×10^{-2} substitutions/site/million years (around one mutation each 200,000 years), closer to the second value used by Thoisie et al., (2010).

Demographic Changes

We used two methods to determine possible demographic changes across the natural history of *T. pinchaque*, *T. terrestris* and “*T. kabomani*” for the three concatenated mitochondrial genes as well as for the *Cyt-b* gene in the lowland tapir. (1) Following the method of Rogers and Harpending (1992) and Rogers et al., (1996) we used a mismatch distribution (pairwise sequence differences). The raggedness rg statistic (Harpending et al., 1993; Harpending, 1994) was used to determine the similarity between the observed and the theoretical curves. (2) We used the Fu and Li D and F tests (Fu and Li, 1993), the Fu F_s statistic (Fu, 1997), the Tajima D test (Tajima, 1989) and the R_2 statistic (Ramos-Onsins and Rozas, 2002) to determine possible changes in population size (Simonsen et al., 1995; Ramos-Onsins and Rozas, 2002). All of these statistics and tests were obtained by means of the DNAsp 5.10 and Arlequin 3.0 programs.

Spatial Structure

Garnering this information can assist in our understanding of the evolutionary events that have determined the natural history of the tapir species. A Mantel's test (Mantel, 1967) was used to detect possible overall relationships between a genetic matrix among individuals (Log-Det genetic distance; Nei and Kumar, 2000) and the geographic distance matrix among the individuals analyzed. In this study, Mantel's statistic was normalized according to Smouse et al., (1986). This procedure transforms the statistic into a correlation coefficient. The geographic distances were measured with the Spuhler's (1972) procedure, where $D = \arccos(\cos X_{(i)} \cdot \cos X_{(j)} + \sin X_{(i)} \cdot \sin X_{(j)} \cos |Y_{(i)} - Y_{(j)}|)$, where $X_{(n)}$ and $Y_{(n)}$ are the latitude and longitude of the n th individual sampled, respectively. The significance of the correlations obtained was tested using a Monte Carlo simulation with 1,000 permutations. This test was undertaken by means of the software NTSYS v. 2.1 (Rohlf, 2000). This analysis was carried out for *T. pinchaque*, *T. bairdii* and the overall sample of *T. terrestris* for the three concatenated mitochondrial genes as well as for the different haplogroups found and for different geographical regions at the *Cyt-b* gene for *T. terrestris*. For all the Amazon *T. terrestris* individuals sequenced at the *Cyt-b* gene, an AIDA analysis was used (Bertorelle and Barbujani, 1995). The expressions of the respective AIDAs coefficients are as follows:

$$H = (n \sum_{i=1 \text{ to } n} \sum_{j>i \text{ to } n} w_{ij} \sum_{k=1 \text{ to } S} (p_{ik} - p_k) (p_{jk} - p_k)) / (W \sum_{i=1 \text{ to } n} \sum_{k=1 \text{ to } S} (p_{ik} - p_k)^2)$$

and

$$CC = ((n - 1) \sum_{i=1 \text{ to } n} \sum_{j > i \text{ to } n} w_{ij} \sum_{k=1 \text{ to } S} (p_{ik} - p_{jk})^2) / (2W \sum_{i=1 \text{ to } n} \sum_{k=1 \text{ to } S} (p_{ik} - p_k)^2)$$

where n is the sample size, W is the number of pairwise comparisons of a distance class given, p_{ik} and p_{jk} are the haplotypes of the i th and j th individuals, respectively. At the k th nucleotide site, p_k is the k th element of the average vector and w_{ij} is one if individuals i and j are within the same distance class; otherwise it is zero. Summation includes the Σ nucleotide sites for all the n individuals analyzed. To connect the individuals sequenced within each distance class, the Gabriel-Sokal network (Gabriel and Sokal, 1969; Matula and Sokal, 1980) and the Delaunay's triangulation with elimination of the crossing edges (Ripley, 1981; Upton and Fingleton, 1985; Isaaks and Srivastava, 1989) were used. However, the results were very similar in each case. The Bonferroni (Oden, 1984), Oden's Q and the Kooijman's tests were estimated to determine the statistical significance of the autocorrelation coefficients.

RESULTS

Gene Diversity, Genetic Heterogeneity and Phylogenetic Considerations for the Latin American Tapir Taxa

The GTR with gamma distributed rate variation among sites for both the maximum likelihood and the AIC criteria was the best fit nucleotide substitution model at the three concatenated genes.

Out of 4,753 comparisons among the total polymorphic sites at the *Cyt-b* gene in *T. terrestris*, only 303 comparisons were statistically significant by means of a Fisher exact test (6.4 %), but they were not different from the Type I error of 5 %. Similarly, the values of the statistics of Kelly (1997) ($ZnS = 0.0219$; 95 % of Confidence interval, $CI = 0.01498 - 0.31650$), of Rozas et al., (2001) ($Za = 0.0244$; $CI = 0.01706 - 0.32607$) and $ZZ = 0.0026$ ($CI = -0.05363 - 0.05625$) also showed that there was no significant association among the polymorphic sites at this mitochondrial gene. Therefore, no evidence of linkage among polymorphic sites was detected at this mitochondrial gene. Out the four taxa of *Tapirus* considered at the three concatenated mitochondrial genes, clearly *T. terrestris* showed the highest levels of gene diversity ($H_d = 0.985$; $\pi = 0.0094$; $k = 22.98$), followed by *T. pinchaque* ($H_d = 0.957$; $\pi = 0.0041$; $k = 9.98$). In contrast, "*T. kabomani*" ($H_d = 0.900$; $\pi = 0.0033$; $k = 8.00$) and *T. bairdii* ($H_d = 0.910$; $\pi = 0.0017$; $k = 4.08$) yielded the lowest levels of gene diversity (Table 1). The "*T. kabomani*" gene diversity should be enclosed within the gene diversity of *T. terrestris* (proof 1). The genetic heterogeneity among these four taxa was highly significant and of a large magnitude for all the statistics used (for instance, $\gamma_{ST} = 0.808$ and $F_{ST} = 0.903$; Table 2a), with the associated indirect gene flow values practically non-existent ($N_m = 0.05-0.12$).

Table 1. Gene diversity statistics for *Tapirus terrestris*, *T. pinchaque*, *T. bairdii* and the alleged new species “*T. kabomani*” at the mitochondrial genes sequenced (*Cyt-b* + *COI* + *COII*). The statistics estimated were the number of haplotypes (NH), the haplotypic diversity (H_d), the nucleotide diversity (π), the average number of nucleotide differences (K) and the θ statistic ($= 2N_e\mu$; N_e = effective female population size; μ = mutation rate per generation) by sequence

	NH	H_d	π	K	θ per sequence
<i>Tapirus terrestris</i>	24	0.985 ± 0.014	0.0094 ± 0.0007	22.985 ± 10.42	29.538 ± 9.448
<i>Tapirus pinchaque</i>	31	0.957 ± 0.021	0.0041 ± 0.0005	9.981 ± 4.648	13.652 ± 4.161
“ <i>Tapirus kabomani</i> ”	4	0.900 ± 0.161	0.0033 ± 0.0009	8.000 ± 4.483	7.680 ± 4.165
<i>Tapirus bairdii</i>	9	0.910 ± 0.068	0.0017 ± 0.0003	4.077 ± 2.173	5.156 ± 2.268

Table 2. Genetic heterogeneity statistics applied to Latin American tapirs: among four Latin American tapir taxa (*T. pinchaque*, *T. terrestris*, *T. bairdii* and the alleged new species “*T. kabomani*”) (2A); between *T. pinchaque* and *T. terrestris* (2B). *Significant Probability ($P < 0.01$)

Table 2A. Among four Latin American tapir taxa

Genetic differentiation estimated	P	Gene flow	
$\chi^2 = 279.000$ df = 201	0.0002*		
$H_{ST} = 0.0287$	0.0000*	$\gamma_{ST} = 0.8079$	Nm = 0.12
$K_{ST} = 0.8026$	0.0000*	$N_{ST} = 0.9078$	Nm = 0.05
$K_{ST}^* = 0.3433$	0.0000*	$F_{ST} = 0.9034$	Nm = 0.05
$Z_S = 941.8106$	0.0000*		
$Z_S^* = 6.4554$	0.0000*		
$S_{nn} = 1.0000$	0.0000*		

Table 2B. *T. pinchaque* sample vs. *T. terrestris* sample

Genetic differentiation estimated	P	Gene flow	
$\chi^2 = 104.041$ df = 70	0.0052*	$G_{ST} = 0.0411$	Nm = 11.68
$H_{ST} = 0.0414$	0.0004*	$\gamma_{ST} = 0.4389$	Nm = 0.64
$K_{ST} = 0.4167$	0.0000*	$N_{ST} = 0.5158$	Nm = 0.47
$K_{ST}^* = 0.2421$	0.0000*	$F_{ST} = 0.5145$	Nm = 0.47
$Z_S = 678.8785$	0.0000*		
$Z_S^* = 6.1920$	0.0000*		
$S_{nn} = 0.7876$	0.0000*		

In another heterogeneity analysis, *T. pinchaque* was only analyzed with regard to *T. terrestris* (Table 2b). In this case, the seven genetic heterogeneity tests were also highly significant at the $P < 0.05$ level. The relative genetic differentiation tests yielded elevated amounts of genetic heterogeneity between the *Tapirus* taxa ($\gamma_{ST} = 0.439$ and $F_{ST} = 0.514$). The gene flow estimates were clearly lower than 1 ($Nm = 0.47$ - 0.64), which showed that these taxa

are genetically disconnected. Although, “*T. kabomani*” showed significant differences with *T. terrestris* as well as with *T. pinchaque*, the genetic differences with *T. terrestris* are considerably lower than with *T. pinchaque* (six significant heterogeneity tests, $\gamma_{ST} = 0.151$ and $F_{ST} = 0.454$, $Nm = 2.82-0.60$ versus seven significant heterogeneity tests, $\gamma_{ST} = 0.300$ and $F_{ST} = 0.711$, $Nm = 1.16-0.20$, respectively). Therefore, “*T. kabomani*” is less differentiated genetically speaking from *T. terrestris* than from *T. pinchaque* and it showed less differentiation in regard to *T. terrestris* than the genetic differentiation between *T. terrestris* and *T. pinchaque*. This provides strong evidence (proof 2) that “*T. kabomani*” is more closely related to *T. terrestris* than to the other tapir species, which disagrees with the point of view of Cozzuol et al., (2013).

The genetic structure within *T. terrestris* is much more robust (greater) than within *T. pinchaque*. This is verified by the consensus MP tree (Figure 2). *T. pinchaque* showed some small geographical clusters with several individuals of nearby geographical regions. Within *T. pinchaque* there were five Colombian individuals (four from Los Nevados National Park and one from Gaitania, Tolima) and two individuals from the Alto Papallacta River in the Napo Province in Ecuador. It also contained seven Ecuadorian individuals (six from the Napo Province and one from Sangay National Park), two from the Napo Province and an Ecuadorian cluster of six.

The Ecuadorian cluster represented three different Ecuadorian populations. Two *T. pinchaque* sequences were more related to those from *T. terrestris* than to those of the other mountain tapirs. These were the cases of one Colombian individual from La Planada, Tolima (Colombia) and one Ecuadorian individual from Chaco, Oyacachi, Napo. However, the relationships among the *T. pinchaque* were considerably less structured than those observed within *T. terrestris*. This second species was composed by more robust haplogroups than those detected in the mountain tapir. Even an exact probability test with a Markov chain length of 100,000 steps only revealed one significant population comparison pair: Los Nevados vs. Sangay National Park ($p = 0.0297 \pm 0.0013$) out of the six populations of *T. pinchaque* studied. This may indicate that (proof 3) *T. terrestris* is an older species than *T. pinchaque*.

The most developed genetic structure in *T. terrestris* can be seen in the AMOVA analyses carried out. The first AMOVA, with the six haplogroups, showed that the major part of the genetic variance was among lineages (64%; $\Phi_{sc} = 0.762$, P-value = 0.000 ± 0.00), followed by the gene variance among the individuals (36%; $\Phi_{st} = 0.641$, P-value = 0.000 ± 0.000). In contrast, the genetic variance among the three main groups (North, Amazonian and South) did not show significant variance (0%, $\Phi_{ct} = -0.510$, P-value = 1.000 ± 0.000). However, in the second AMOVA, by geographical areas within the Amazon basin, the major part of the genetic variance was explained by the difference among the individuals (90%, $\Phi_{st} = 0.499$, P-value = 0.000 ± 0.000). The genetic variance among the populations, although significant, only explained 10 % of the genetic variance ($\Phi_{sc} = 0.148$, P-value = 0.000 ± 0.000). The gene variance between the two main groups was again not significant (0%, $\Phi_{ct} = -0.057$, P-value = 0.913 ± 0.008).

The lower gene variance among geographical regions relative to among haplogroups is explained because the diverse haplogroups coexisted sympatrically at the same points of the Northern Peruvian Amazon (four out of six different haplogroups). This was also true for the Colombian Amazon (six of six), Northwestern Brazilian Amazon (three out of six), Southern Peruvian Amazon (three out of six) and Bolivian Amazon (three out of six). The existence of

extremely, well-differentiated haplogroups within *T. terrestris* could help us to understand why “*T. kabomani*” is an additional haplogroup within “*T. kabomani*” rather than a full species (proof 4). An ML tree, applied to *T. terrestris* at the *Cyt-b*, showed that six haplogroups were detected within this species (Figure 3). The SOWH tests (and also the SH tests) indicated that there was neither support for the taxonomic schemes of 1 to 5 clusters nor for the 7 to 10 clusters. The maximum likelihood trees were significantly different at the 0.001 level (since 12,569 to 689,999 log likelihood units). However, the scheme suggested that six clusters did not significantly deviate from the tree we obtained (1,455 log likelihood units, $p < 0.55$).

Figure 2. Consensus maximum parsimony tree with 45 *Tapirus pinchaque*, plus 17 *T. terrestris* by using the concatenated sequences of three mitochondrial genes (*Cyt-b* + *COI* + *COII*).

Figure 3. Maximum likelihood (ML) tree with the 80 haplotypes (from haplotype 2 to haplotype 81) found at the *Cyt-b* gene (1,140 bp) for the 141 lowland tapirs sequenced analyzed. Numbers in the nodes are bootstrap percentages.

Table 3 shows the Kimura 2P genetic distances among all of the Neotropical *Tapirus* taxa. For all three genes, “*T. kabomani*” yielded lower genetic distances with regard to *T. terrestris* than did *T. pinchaque* (*Cyt-b*: 0.018 ± 0.003 vs. 0.024 ± 0.003 ; *COI*: 0.005 ± 0.002 vs. 0.010 ± 0.004 ; *COII*: 0.013 ± 0.003 vs. 0.017 ± 0.004 , respectively). The genetic distances between “*T. kabomani*” and *T. terrestris*, typical of different populations within a species, are not surprising results. However, the small genetic distances between what are traditionally considered full species (*T. terrestris* and *T. pinchaque*) are (proof 5).

Table 3. Kimura 2P genetic distance (Kimura, 1980), in percentages, with standard deviations among Neotropical *Tapirus* taxa pairs for three mitochondrial genes (*COI*, *COII* and *Cyt-b*)

Figure 4 shows the ML tree for the three concatenated mitochondrial genes with the "*T. kabomani*" sequences (both Brazilian individuals reported by Cozzuol et al., 2013 and three specimens sampled by us). Clearly, our tree with 93 specimens showed reciprocal monophyly between *T. terrestris* and *T. pinchaque*. Moreover, the alleged "*T. kabomani*" is, mitochondrially speaking, a clade within *T. terrestris*. Thus, our results do not provide positive data in favor of *T. kabomani* as a new and full tapir species (proof 6). The ML tree with only the barcoding gene *COI* employed for species discrimination, also showed "*T. kabomani*" as a clade within *T. terrestris* (Figure 5; proof 7). This demonstrates reciprocal monophyly between *T. terrestris* and *T. pinchaque*.

The MNJ procedure including the four possible Latin American tapir taxa for the three concatenated genes (Figure 6) showed that the haplotype sets of *T. bairdii*, *T. terrestris* and *T. pinchaque* are well defined. However, the "*T. kabomani*" haplotypes seem to be an extreme extension from those of *T. terrestris* (proof 8).

An individual of *T. terrestris* from the Chiquitania in Bolivia (this was not reflected in any phylogenetic tree) connected the "*T. kabomani*" and *T. pinchaque* haplotypes. Some temporal split estimations were estimated by this procedure and they are interesting and cited here. For example, the temporal split between *T. bairdii* and *T. terrestris* and *T. bairdii* and "*T. kabomani*" were $7,960,000 \pm 69,282$ YA ($\rho = 39.8 \pm 0.346$) and $9,560,000 \pm 144,222$ YA ($\rho = 47.8 \pm 0.721$), respectively. Therefore, on average, the time split between *T. bairdii* and *T. terrestris* + "*T. kabomani*" was around 8.76 MYA. The temporal split between *T. terrestris* and *T. pinchaque* was around $3,420,000 \pm 509,117$ YA ($\rho = 17.1 \pm 2.545$) and the haplotype diversifications within both species were $3,300,000 \pm 141,421$ YA ($\rho = 16.5 \pm 0.707$) and $1,208,696 \pm 194,635$ YA ($\rho = 6.04 \pm 0.973$), respectively. In consideration of these data, the mitochondrial diversification of *T. terrestris* preceded *T. pinchaque* and/or being the subsistence of the original haplotypes in *T. terrestris* higher than in *T. pinchaque*. This last possibility agrees quite well with the fact that the gene diversity is lower in *T. pinchaque* than

in *T. terrestris*. This is probably more due to the greater action in gene drift associated with considerably small population sizes in the first species rather than in the second species. The temporal split between *T. terrestris* and “*T. kabomani*” was around $1,300,000 \pm 360,555$ YA ($\rho = 6.5 \pm 1.802$), considerably lower than that between *T. terrestris* and *T. pinchaque*, ratifying “*T. kabomani*” as a clade within *T. terrestris* (proof 9).

Figure 4. Maximum likelihood (ML) tree for 93 Neotropical tapir specimens (including *T. pinchaque*, *T. terrestris*, *T. bairdii* and the alleged new species, “*T. kabomani*”, reported by Cozzuol et al., 2013) for three concatenated mitochondrial genes (*Cyt-b* + *COI* + *COII*). *T. kabomani* was within the *T. terrestris* clade and therefore these mitochondrial genes did not provide positive evidence for *T. kabomani* as a full species.

Figure 5. Maximum likelihood (ML) tree for different individuals of the three Neotropical tapir species recognized and the alleged new species reported as “*T. kabomani*” by Cozzuol et al., (2013) at the *COI* gene. “*T. kabomani*” was a clade within *T. terrestris*.

The MJN applied only to *T. terrestris* at the *Cyt-b* gene showed the following picture (Figure 7). There were six well-defined haplogroups. Amazon 0 (which corresponds to “*T. kabomani*” in the other analyses) and Amazon I haplogroups were the most differentiated ones.

The average temporal split among the six haplogroups was around 1.6 ± 0.34 MYA. The beginnings of the temporal diversification within each haplogroup were as follows: 0.59 MYA for the Amazon I, 0.42 MYA for Amazon II and Amazon III, 0.55 MYA for the North and 0.33 MYA for the South.

Figure 6. Median Joining Network (MJN) with the mitochondrial haplotypes found for *Tapirus bairdii* (green), *T. terrestris* (yellow), “*T. kabomani*” (brown) and *T. pinchaque* (blue) with the concatenated sequences of three genes (*Cyt-b* + *COI* + *COII*). Red circles are intermediate haplotypes not found. “*T. kabomani*” was a prolongation of *T. terrestris*.

Figure 7. Median Joining Network (MJN) with the 80 haplotypes found at the Cyt-b gene for the 141 lowland tapirs analyzed. Six different mitochondrial haplogroups were found (Amazon 0, I, II, III, North and South). The Amazon 0 haplogroup corresponds to “*T. kabomani*”. Red circles indicate missing intermediate haplotypes.

Demographic Changes in Latin American Tapirs

The mismatch distribution for *T. pinchaque* (Figure 8) showed no clear demographic changes of the total sample or in the Colombian population. But, it did show a significant curve related to a population expansion for the Ecuadorian sample ($rg = 0.006$, $p = 0.011$). For the Ecuadorian population, this expansion began around 2,900 years ago and the initial population size could have been around 4,770–6,691 females. Four of the five demographic change tests (Tajima's D , Fu & Li D^* and F^* , Fu's F) were significant for the total sample. However, the Ramos-Onsins & Rozas R_2 test was not significant for any of the three samples (Table 4).

(b)

Ecuadorian *T. pinchaque* sample (population expansion)

Figure 8. (Continued).

Figure 8. Historical demographic analyses by means of the mismatch distribution procedure (pairwise sequence differences) for the mitochondrial DNA studied in *Tapirus pinchaque*. These analyses were applied to: Overall *Tapirus pinchaque* sample (A); Colombian mountain tapir sample (B); Ecuadorian mountain tapir sample (C).

The mismatch distribution and the six demographic tests carried out showed a clear population expansion for the overall *T. terrestris* sample studied (Figure 9 and Table 5). All six tests were highly significant. There was clear evidence of population expansion in different haplogroups. For Amazon I, the mismatch distribution and two out of six tests were significant.

This was the haplogroup where there was less evidence of demographic change. For Amazon II, III and North, the mismatch distribution and four out of six tests were significant. For South, the mismatch distribution and five out of six tests were significant. Thus, we determined noteworthy evidence of population expansion within each haplotype lineage as well as for the total *T. terrestris* distribution. When we only considered two geographical groups (North and South of the Amazon River), there was also strong evidence of population expansion. For the Southern Amazon group, the mismatch distribution and six out of six tests were significant, whereas for the Northern Amazon group, the mismatch distribution and four out of six tests were significant.

Although, the sample of “*T. kabomani*” is modest, we also analyzed possible demographic changes in this taxon (Figure 9 and Table 5). The mismatch distribution and two out of six demographic tests showed evidence of population expansion such as was observed in *T. terrestris*, especially in the Amazon I haplogroup.

Thus, “*T. kabomani*” should be a dynamic demographic extension of *T. terrestris*, characterized by historical population expansions (proof 10).

Figure 9. Historical demographic analyses by means of the mismatch distribution procedure (pairwise sequence differences) for the mitochondrial DNA studied in *Tapirus terrestris* and "*T. kabomani*". These analyses were applied to: Total *T. terrestris* sample (A); Amazon I, Amazon II, Amazon III, North, and South (B); Northern bank of the Amazon River and Southern bank of the Amazon River (C); "*T. kabomani*" (D).

Spatial Structure

For *T. pinchaque*, the overall Mantel test between the log (genetic distance) and the log (geographic distance) showed $r = -0.127$ ($p < 0.691$ from 10,000 randomizations). Therefore, there is no measureable spatial genetic structure in *T. pinchaque*, at least, in the areas sampled in Colombia and Ecuador for mitochondrial DNA. Similarly, for *T. terrestris*, the Mantel test did not detect any significantly positive correlation between the genetic distances and the geographical distances among the exemplars sampled at the global level, within different haplogroups and within certain geographical regions at the *Cyt-b* gene. Some correlations were significant but negative (for the global tapir population studied, $r = -0.169$, $p = 0.001$; Amazon I, $r = -0.439$, $p = 0.001$; Amazon II, $r = -0.213$, $p = 0.001$; Amazon III, $r = -0.107$, $p = 0.023$; North, $r = 0.007$, $p = 0.439$; South, $r = -0.525$, $p = 0.001$; total Colombia, $r = -0.070$, $p = 0.007$; Northern Colombia-Venezuela, $r = -0.134$, $p = 0.001$). Therefore, no isolation by distance patterns were found in any of the *T. terrestris* groups analyzed. Nevertheless, for *T. terrestris*, an AIDA analysis for the entire Amazon basin showed the 1 DC (0-350 km) to be significantly positive. The 4 DC (1,150-1,350 km) had a significantly negative autocorrelation and again a significantly positive autocorrelation at 6 DC (1,500-1,700 km). This correlogram showed the typical resemblance of a double circular cline (Sokal and Oden, 1978), which implied a complex pattern of colonization of this area by the lowland tapir.

In contrast, the *T. bairdii*'s haplotypes showed a very significant spatial genetic trend ($r = 0.819$, approximate Mantel t-test = 3.611, $p = 0.0002$; out of 5000 random permutations, 5000 were $< Z$, $0 = Z$ and $0 > Z$; one-tail probability $p = 0.0004$), an effect of isolation by distance.

DISCUSSION

Genetic Conservation of the Latin American Tapirs

Clearly, *T. terrestris* had the highest gene diversity level of all tapir species. This finding agrees quite well with the fact that the Latin American *Tapirus* species had the widest geographical distribution and therefore the highest potentially effective numbers. Curiously, *T. pinchaque*, a species with a very restrictive geographic distribution and a small population size, presented a gene diversity that was more than three times higher than that of *T. bairdii*. The surprise is due to the fact that *T. pinchaque*, may be on the brink of extinction (Ashley et al., 1996) whereas *T. bairdii*, has historically occupied a distribution from Southern Mexico to the Pacific area of Colombia and maybe Ecuador (Tirira, 2011). Thus, although *T. pinchaque* has a very small census population size and a very restrictive geographical distribution, within disturbed and fragmented ecosystems, the species is not impoverished from a genetics point of view. This is good news from conservation perspective.

The geographical distribution of *T. pinchaque* is still not completely known and there is disagreement over its distribution within the scientific literature. In Colombia, populations of the mountain tapirs are well described in the Central and Eastern Cordilleras (Lizcano et al., 2002; Cavelier et al., 2010). Lizcano et al., (2002) estimated around 2,500 mountain tapirs in Colombia with around 1,874 animals in seven Colombian National Parks. However, Cavelier et al., (2010) estimated a minimum of 543 specimens and a maximum of 579 animals in the

eight Colombian National Parks where they considered that this species still lives. However, the presence of the mountain tapir in the Western Colombian Cordillera is disputed. Acosta et al., (1996) and Downer (1997) recorded locations in this Cordillera where the species could have lived in the past. Sarriá (1993) recorded comments of staff working at Farallones de Cali National Park who observed *T. pinchaque* near Alto de Pance and Alto del Hambre (3,730 masl). Another possible record of the presence of *T. pinchaque* within the Western Cordillera was made by De Wilde (1994), who wrote about footprints in the Caramanta Cerro between the Departments of Antioquia and Risaralda. However, Lizcano et al., (2002) suggested that this species does not inhabit the Western Cordillera. Furthermore, Lizcano and Cavelier (2000) considered that such records within the Western Cordillera may indicate the Baird's tapir (*T. bairdii*) and not *T. pinchaque*. The Baird's tapir could also live within the montane forest of Central America, up to 3,000 masl. However, Arias-Alzate et al., (2010) recently reported the existence of a skull of a *T. pinchaque* in a Medellín museum sampled in 1911 from Páramo de Frontino in the Antioquia Department of Western Cordillera. This provides evidence of *T. pinchaque* living within the northern area of the Western Cordillera.

Lizcano et al., (2002) recorded the presence of the mountain tapir within the Central Cordillera from Los Nevados National Park (Caldas and Risaralda Departments) to the South. They also noted the mountain tapir within the Eastern Cordillera from Páramo de Sumapaz to the South. However, some populations of mountain tapir have been recently detected north of Páramo de Sumapaz within the Eastern Cordillera, including at Chingaza National Park and 12 other northern localities. Páramo de Pisba may be one of these sites (Montenegro, 2002). The current absence of mountain tapirs from Northern Central and Eastern Cordilleras could be the result of hunting activity (Lizcano et al., 2002). The extreme decline of the female population we detected for the Colombian *T. pinchaque* population at the genetic level with a Bayesian sky plot analysis (Ruiz-García et al., 2015b) correlated quite well with the fact of an extreme reduction in the potential habitat space of the Andean tapirs. Cavelier et al., (2010) showed that the current distribution for Andean tapirs covers 31,400 km², compared to 205,000 km² in the past. Similarly, the trend in distribution size for tapirs in Colombia is much lower today (14,385 km²) than in the past (74,556 km²). That is, the current value corresponds to 19% of the past distribution. The area where the species occurs is actually a collection of 35 forest patches. Most of the fragments are small and only four are larger than 1,000 km² (Lizcano et al., 2002). These authors showed that only five to six fragments have the minimum necessary size (826 km²) to maintain at least 150 individuals, the estimated number to maintain a viable population in the short term. Thus, the situation of *T. pinchaque* is critical in Colombia.

In Ecuador, the areas with the highest *T. pinchaque* population sizes are the Cayambe-Coca National Park (Northern Eastern Cordillera) and the Sangay National Park (Central Eastern Cordillera). There are other areas of Ecuador, such as the Reserva Ecológica El Ángel (Carchi Province), Cajas National Park-Bosque Protector Mazán (Azuay Province) and the Condor Cordillera, where the mountain tapirs have lived but where there are no records of them in the last few decades (Downer, 1997; Tirira and Castellanos, 2001).

Cavelier et al., (2010) estimated a population size of 543-579 individuals for Colombia and 983-1,047 individuals for Ecuador. However, the gene diversity of *T. pinchaque* in Colombia is higher than in Ecuador. Dobzhansky (1971) showed that ancestral populations retain more elevated gene diversities than do derived populations. This may support that the original *T. pinchaque* population inhabited the Colombian Andean Mountains and later it expanded toward the southern mountains (Ecuador today). Our analyses detected the population expansion of the

Ecuadorian population. However, more recently, the Colombian population decreased due to hunting and habitat fragmentation (high population decrease in the last 5,000 YA; Ruiz-García et al., 2015b). The Ecuadorian population has been less affected by human activity. Thus, the Colombian population could be in a more dangerous situation than the Ecuadorian population. Another *T. pinchaque* population in critical situation should be the Peruvian population. Cavelier et al., (2010) only estimated between 41 to 43 mountain tapirs in the Peruvian protected Tabaconas Namballe National Sanctuary. Downer's (1997) work suggests the possibility of mountain tapirs inhabiting Eastern Tapal in the Cajamarca Province, south of the Jaén Province, and at the Piura Province. The Peruvian population needs a molecular population analysis.

The gene diversity levels of *T. terrestris* are the highest estimated for the Latin America tapirs and this species seems to not be significantly endangered from a genetics point of view. Also, the major part of the haplogroups showed historical population expansions. However, *T. terrestris* is a species threatened due to the subsistence hunting carried out by the Indian and "colonos" communities in South America. Another threat comes from the deforestation of the Neotropical forests due to extensive agriculture and ranching (Constantino et al., 2006). In many areas of South America, this species is more targeted than other animals by hunters. Here we provide three examples of hunting: 1- Our first example is the case of 22 Indian Izoceño-Guaraní communities in the "chaqueña" region of Bolivia, who intensively hunt tapirs (Barrientos and Cuéllar, 2003); 2-A second example is the case reported by Romero et al., (2013) in the community of Caura (Guarataro), along the Southern Orinoco River in Venezuela. There humans consume 40% of their proteins from hunted animals. Of the 196.6 g of proteins consumed by a human per week, 77 g originated from wild hunts and of these, 14 were from tapirs. Out of 184 tons of wild meat consumed in a year, 44 tons were from tapirs. This means that in one year this community hunted 274 tapirs. 3- Third, it is clear that the tapir provided the most meat in the Peruvian rainforest compared to all other mammals, but unfortunately the hunting model used is non-sustainable. Bodmer et al., (1997a) calculated the percentage of production taken by hunters in the Pacaya-Samiria National Park within the Peruvian Amazon. For example, the hunted red deer (*Mazama americana*), collared peccary (*Pecary tajacu*) and white lipped peccary (*Tayassu pecari*) yielded values of 6.8%, 4.3% and 19.8%, respectively. The authors considered that a value higher than 20% could be dangerous to the continued subsistence of a population. The value for the lowland tapir in that Peruvian area was 166%, which showed that the probability of subsistence of that population was completely unsustainable. Also, Bodmer et al., (1997b) showed that in one year for three areas of the Pacaya-Samiria National Park, 53 *Tayassu pecari*, 12 *Pecari tajacu*, 13 *Mazama Americana* and 20 *Tapirus terrestris* were killed. But, tapir species have the highest biomass (4,000 kg) of all mammals, making up 48% of the ungulate biomass extracted and 35% of the total mammal biomass extracted. Thus, tapirs are critically affected by hunting. Furthermore, this species has a long gestation period of around 13 months, only producing one offspring by litter (Padilla and Dowler, 1994). Tapirs reach sexual maturity at two years of age (Yamini and Schillhorn, 1988), and females only have one offspring every three years. Tapirs also have a very low population density (Bodmer and Brooks, 1997; Bodmer et al., 2000). Bodmer and Brooks (1997) reported an overall density of 0.4 ind/km² for the Peruvian Amazon forests, while Ayala (2003) found a value of 0.5 ind/km² for the Bolivian Chaco. Scientists have offered a range of estimations from 0.028 ind/km² in the Northern Colombian Amazon (Chamorro-Rengifo and Cubillos-Rodriguez, 2007) to 1.2-1.6 ind/km² in the Chiquitanian forest of Bolivia (Arispe et

al., 2007) and Brazil (Schaller, 1983). For this reason, the conservation of tapirs is crucial within Neotropical environments.

The reduction of the lowland tapir populations is observable because of its markedly reduced distribution. One example of this is the putative subspecies *T. t. colombianus*, that has been extirpated from the lowlands of the Caribe region as well as from the Andean valleys of Colombia. This putative subspecies has been isolated in some localities of the Sierra Nevada de Santa Marta (Constantino et al., 2006). *T. terrestris* is classified in the Appendix II of CITES and the IUCN (2003) classified it as Vulnerable. Also, the subspecies, *T. t. colombianus*, is considered to be Critically Threatened (IUCN, 2004). In northern Argentina, the tapir distribution range has been reduced by 46% in the last century by hunting and habitat destruction (Chalukian et al., 2013).

Thoisy et al., (2010) affirmed that the Amazon River acted as a barrier to gene flow in *T. terrestris*. Our results showed that the Amazon River was only a partial barrier for haplotype dispersion for *T. terrestris*. An interesting additional comment related with this is that the jaguar corridor initiative proposed by Rabinowitz and Zeller (2010) and Zeller et al., (2013) could be very useful for the lowland tapirs too. The jaguar conservation units could be very similar and overlap the region with the largest tapir populations (they are the largest carnivore and herbivore mammals in South America). The 182 jaguar corridors proposed by these authors (2.6 million km²) could also be useful in connecting tapir populations especially in the northern and southern geographical areas of South America where the habitat destruction carried out by humans is more intense.

The case of *T. bairdii* seems to be even more dramatic. Although its geographic distribution is wide, it has been dramatically reduced and fragmented in the last two centuries and today no more than 6,000 individuals are left in the wild (Ashley et al., 1996). Its mitochondrial genetic diversity levels were extremely low compared with other Neotropical tapirs. This could mean that this species suffered from a bottleneck and/or the gene drift has been more intense on this species by natural or human constrictions. Indeed, this species has intensely declined in the last century by habitat destruction and hunting and has been extinct in El Salvador and in a major fraction of its original distribution range in Colombian and probably completely extinct in Ecuador (Bodmer and Brooks, 1997).

Systematics of the Neotropical Tapirs and the Case of the Alleged “*T. Kabomani*”

All the molecular studies on tapirs, with the exception of that of Couzzol et al., (2013) and one of the analyses of Thoisy et al., (2010), determined the split between *T. terrestris* and *T. pinchaque* to have occurred during the last Pliocene or at the beginning of the Pleistocene. Ashley et al., (1996), analyzed the *COII* gene and determined the temporal split between the ancestors of *T. terrestris* and *T. pinchaque* to be around 3 MYA. The authors concluded that this coincided with the disappearance of the Bolivar Trough and the apparition of the modern Panamanian isthmus. Norman and Ashley (2000) added more *Perissodactyla* species and other mitochondrial gene (*12S rRNA*) and estimated new temporal splits. The *COII* and *12SrRNA* genes supported divergence times between *T. terrestris* and *T. pinchaque* of 2.5-2.7 MYA and 1.5-1.6 MYA, respectively. More recently, Ruiz-García et al., (2012), analyzed the *Cyt-b* gene and showed a Bayesian tree where the ancestors of *T. terrestris* and *T. pinchaque* diverged

around 3.8 MYA (95% High Posterior Density, HPD: 2.1-4.7 MYA). When a ρ statistic was used on a MNJ network, the two most frequent *T. terrestris*'s haplotypes diverged from the main *T. pinchaque*'s haplotype around 1.58 ± 0.30 MYA and 1.53 ± 0.34 MYA, respectively. Ruiz-García et al., (2015a) showed a Bayesian tree that supported a temporal split of 3.33 MYA between both *T. pinchaque* and *T. terrestris*. Also, Ruiz-García et al., (2015b) performed a mitogenomic study of *T. pinchaque* and determined the temporal split between the ancestors of *T. terrestris* and *T. pinchaque* to oscillate from 7.42 to 3.27 MYA (95% HPD) in a Bayesian tree. In that study also, with the ρ statistic from the MNJ analysis, and with no priors from other paleontological or molecular studies, assuming that *T. pinchaque* was an ancestral taxon with regard to *T. terrestris* (the Hershkovitz, 1954's and Haffer 1970's hypotheses), a split occurred between the taxa around 2.47 ± 0.42 MYA. In contrast, if *T. terrestris* is older than *T. pinchaque*, (Ruiz-García et al., 2012's hypothesis), the temporal divergence between them would have occurred around 3.59 ± 0.79 MYA. Our current work suggests that the split between species occurred 3.4 MYA.

These temporal estimates absolutely disagree with what Cozzuol et al., (2013) claimed. They reported a temporal split within the clade "*T. kabomani*"-*T. pinchaque*- *T. terrestris* ranging from 0.65 to 0.29 MYA (95% HPD, with the split between *T. pinchaque* and *T. terrestris* around 0.1-0.3 MYA following these authors). In another approach, Thoisy et al., (2010), estimated the divergence between *T. terrestris* and *T. pinchaque* to have occurred around 0.33 MYA.

Nevertheless, we are more confident that the first estimates are more accurate than the second for three main reasons. (1) In the current work we used more individuals of all the Latin American tapir taxa and more genes (better gene diversity estimations in each taxa) than the Thoisy et al., (2010)' work. However, we used a mutation rate, in our MJN analysis that was close to the second mutation rate used by Thoisy et al., (2010). They obtained a very recent split between *T. pinchaque* and *T. terrestris* (0.33 MYA). The temporal split estimates provided by Ruiz-García et al., (2015a,b), ranged from 7.4 to 2.5 MYA. They were obtained without any prior or constriction made by the researchers on divergence times or mutation rates. Our current estimate of 3.4 MYA is within of the quoted range. (2) The extremely reduced divergence time put forth by Cozzuol et al., (2013) for the split among "*T. kabomani*"-*T. pinchaque*- *T. terrestris*, and which influences the appearance of "*T. kabomani*", is easily explained by a temporal constriction imposed by these authors in their data. They applied a constriction for the mitochondrial haplotype diversification in *T. terrestris* of 0.13 ± 0.1 MYA because they affirmed that the oldest fossil records of *T. terrestris* date back to the beginning of the fourth Pleistocene glaciation (0.13 MYA). This paleontological constriction helps to explain the difference in temporal divergence between South American tapir species noted by Cozzuol et al. (2013) relative to other studies. These authors claimed that no clear *T. terrestris* fossil records dating older than 130,000 YA have been located, following Tonni (1992). He described a *T. terrestris*'s mandible from the Lujanense age (upper Pleistocene, 130,000 YA) that he collected from the Colon Department at the Entre Rios Province (Argentina). Also, Noriega et al., (2004) and Ferrero et al., (2007), found fossil fragments of *T. cf. terrestris* corresponding to the El Palmar Formation at the El Boyero locality (upper Pleistocene) at the Entre Rio Province (Argentina). But, this does not mean that they don't exist, simply that they have yet to be found. Recently, Holanda and Rincón (2012) reported two tapir remains in Venezuela. One of them was classified as *T. terrestris* from the Zumbador Cave from the upper Pleistocene,

while the second fossil from El Breal de Orocuál was classified as *Tapirus sp.* It's unclear if this last fossil was from the Pliocene or from the early Pleistocene. For example, if this last remain is classified as *T. terrestris*, the Cozzuol et al., (2013)'s constrictor doesn't make sense and therefore the divergence within the clade "*T. kabomani*"-*T. pinchaque*- *T. terrestris* should be considerably older. Indeed, we believe that some of the oldest South American tapir fossil remains classified as *Tapirus sp.* could belong to *T. terrestris*, especially if a population view is adopted more than a typological one, which is more typical of paleontologists. Hulbert et al., (2009) showed that the discovery of 75 individuals of *T. polkensis* in the Gray Fossil Site in Eastern Tennessee indicated a unique species. However, it had considerable intraspecific variation in the development of the sagittal crest, outline shape of the nasals and the number and relative strength of lingual cusps on the P1. These authors concluded that if these fossil remains had been found in diverse geographical areas, they would have been considered different species. Similarly, Perini et al., (2011) demonstrated that the lower molariform teeth size and proportions, used by many authors to define different tapir fossil species, are unreliable because they have great population variability. Thus, some early and middle Pleistocene tapir fossils should be re-assigned and some of them could be un-differentiated from *T. terrestris*. The findings of Perini et al., (2011) don't support the conclusion that all of these *Tapirus* fossils are *T. terrestris*, they simply indicate that some are not, but that others could be. Indeed, in our population criteria and in a context of anagenesis, or phyletic evolution, some fossil of tapirs, like *T. rondoniensis*, *T. cristatellus* and, even, *T. mesopotamicus* could be interpreted as *T. terrestris* individuals with some small morphological differentiated traits. These traits would probably be due to the exposure to different environmental conditions in each moment and in each Pleistocene refugium as well as due to phenotypic plasticity. Another controversial question between genetics and paleontological findings in regard to tapirs is the fact that several authors, from a paleontological point of view, claimed that the South American tapirs do not form a monophyletic group (Holanda and Ferrero, 2013). These authors maintain that *T. pinchaque*, *T. terrestris*, *T. mesopotamicus*, *T. rondoniensis* and *T. cristatellus* are paraphyletic with evolution in situ in South America—deriving from a similar form such as *T. webbi* from North America during the Miocene. They also claimed that another dispersal event occurred from South America to North America by means of a form similar to *T. cristatellus*, which gave origin to the derived forms of North America. This contrasts with the opinion of other authors such as Hulbert and Wallace (2005) and Hulbert (2010), who maintained that the North American forms were more primitive. From a molecular genetics perspective, Ruiz-García et al., (2012), and the current work, found that the two extant tapir species in South America only belonged to a unique migration wave, whilst *T. bairdii* belonged to another different molecular group, older than the first and probably more related to the fossil tapirs from North America. Thus, the molecular results seem to agree better with the second paleontological hypothesis than with the first one.

3- Within the Perissodactyla order, there are no cases of an appearance of new species in the last 0.1-0.3 MYA. In Equidae, Xu (1996), took into account all of the mitochondrial DNA and estimated the initial splitting within *Equus* to have occurred approximately 9 MYA. Tougaard et al., (2001), by means of the 12S rRNA and Cyt-b genes, determined that time split to be 12.2 ± 2.2 MYA. Recently, Orlando et al., (2013), sequencing more than 5,000 genes, determined that all contemporary horses, zebras and donkeys originated 4.0–4.5 MYA. Furthermore, they determined the divergence time between populations of Przewalski's and domestic horses to be approximately 0.38-0.72 MYA (different horse subspecies). In Rhinocerotidae, the split between the current species is estimated to be around

26 MYA (isoenzymes; Merenlender et al., 1989) and 21.5 MYA (12S rRNA and 16S rRNA genes; Morales and Melnick, 1994). The molecular temporal divergence between the two Asian rhinoceros genera was around 25.9 ± 1.9 MYA (Tougard et al., 2001). Their paleontological estimates oscillated from 16 to 23 MYA (Carroll, 1988). The molecular split for the two Asian rhinoceros species of the genus *Rhinoceros* (*R. sondaicus* and *R. unicornis*) was molecularly estimated to have occurred around 11.7 ± 1.9 MYA (Tougard et al., 2001). Their paleontological split has been estimated to have occurred 1.6-3.3 MYA (Carroll, 1988). The two traditional subspecies of the white rhinoceros (*Ceratotherium simum simum* and *C. simum cottoni*) have been estimated to diverge around 1 MYA (Groves et al., 2010). Henceforth, the claim by Cozzuol et al., (2013) of a divergence time of around 0.1-0.3 MYA between *T. terrestris* and *T. pinchaque* does not agree with that determined for other current Perissodactyla taxa.

With regard to the systematics of *T. pinchaque*, our genetics data make a remarkable contribution. Hershkovitz (1954) found a variable trait in the *T. pinchaque* dentition, as manifested by the first upper premolar, which is variable. Ecuadorian specimens show the simple condition, with the cinguloid shelf absent, whereas the first Colombian *T. pinchaque* skull examined shows the premolar as another *Tapirus* species. For this reason, he distinguished two subspecies (*T. p. pinchaque* and *T. p. leucogenys*) within the mountain tapir. However, our molecular results showed that Colombian and Ecuadorian specimens were mixed independently of their geographical origins disagreeing with the fact that they are different subspecies.

With regard to the systematics of *T. terrestris*, the existence of the six mitochondrial haplotype lineages did not agree at all with the four morphological and geographical subspecies determined by Cabrera (1961) and Hershkovitz (1954). That is, there was no correspondence among the mitochondrial haplogroups and the morphological subspecies. In the geographical area of *T. t. aenigmaticus*, we found the six different haplogroups detected in this study. In the wide distribution of *T. t. terrestris*, four haplogroups were found (Amazon II and III, North and South). Thus, there was no correspondence among the subspecies *T. t. anigmaticus* and *T. t. terrestris* and the mitochondrial lineages herein showed. We tentatively negate the validity of these two subspecies. In the territory of *T. t. colombianus*, two haplogroups were detected, Amazonian II and North. Theoretically, the animals sampled in the Colombian Departments of Antioquia, Córdoba and Magdalena (Sierra Nevada de Santa Marta) and at the Zulia (Maracaibo Lake) in Venezuela belonged to *T. t. colombianus*. However, one animal from the Antioquia Department belonged to the Amazonian II haplogroup. Animals from Meta, Vichada and Guainia Departments (Colombian Eastern Llanos and Amazon), French Guyana, Madre de Dios River (southern Peruvian Amazon), Yavari River (Western Brazilian Amazon) and even animals from Northern Argentina shared haplotypes with the North haplogroup. Therefore, there is no linear correspondence between *T. t. colombianus* and the North haplogroup, which questions the reality of this subspecies. The case of these animals from Northern Argentina within this haplogroup is extremely strange. It could be that animals with the same haplotypes migrated from the upper part of the Western Amazon to the northern and southern distribution ranges. And, for this reason, both extreme geographical areas (Northern Colombia and Northern Argentina) share mitochondrial haplotypes. Another possibility, which must be remotely considered, is the fact that during the XIX century and the beginning of the XX century, people imported tapirs from northern areas of South America and liberated them to Northern Argentina

for game hunting purposes (Martínez, personal communication). This could explain the presence of haplotypes of the North haplogroup in Northern Argentina.

All the animals we sampled in Southern Brazil, Eastern Bolivia and Paraguay, which “a priori” belonged to *T. t. spegazzinni* by its geographical distribution and morphological features, belonged to the South haplogroup. Therefore all the southern animals belonged to a unique mitochondrial haplogroup, with the exception of the Argentinian individuals. In this case, it could be a linear correspondence between the South haplogroup and *T. t. spegazzinni*. However, some animals from the Central Brazilian Amazon and from the Colombian Amazon also showed haplotypes of this South haplogroup. It is also interesting to note that traditionally only *T. t. spegazzinni* has been cited in Bolivia (Anderson 1997). In Bolivia, 35 specimens have been located representing 24 localities (Salazar-Bravo et al. 2003). We found many tapirs of Bolivia belonging to the South haplogroup (related with *T. t. spegazzinii*), but we also determined exemplars of the Mamore River which belonged to the Amazonian II lineage typical of more Northern Amazon areas.

Due to the complex spatial distribution pattern of *T. terrestris* garnered through analysis of the *Cyt-b* gene it is impossible to assign tapirs with unknown origin and living in captivity to precise geographical locations. However, we can assign them to one of the six haplogroups we found. For instance, the five tapirs from the US zoos belonged to three out of the six haplogroups (Amazon I, III and South). Also, the exemplar sampled at the Barcelona Zoo belonged to the South haplogroup. Moreover, the animal of unknown origin we analyzed was assigned to the North haplogroup. It was a unique tooth that had no recorded origin. This complex spatial structure could complicate the application of some biological conservation concepts, such as ESUs (Evolutionary Significant Units) and MUs (Management Unit) (Moritz and Faith, 1998) to *T. terrestris*.

Our mitochondrial data totally disagree with the results of Cozzuol et al., (2013). They claimed that “*T. kabomani*” was a full species. We provide 10 population genetics proofs against this claim. All of our trees, as well as those from Ruiz-García et al., (2015a,b,c) showed that “*T. kabomani*” is a particular lineage within *T. terrestris*. In a mitogenomic study with 15 genes and more than 250 *T. terrestris* individuals, Ruiz-García et al. (2015c) showed reciprocal monophyly between *T. terrestris* and *T. pinchaque*. Also, “*T. kabomani*”, together with the Amazon I haplogroup, were the first haplogroups to diverge within *T. terrestris*. In the current work, with three mitochondrial genes, the genetic distances between *T. terrestris* and “*T. kabomani*” were always lower than the genetic distances obtained between *T. terrestris* and *T. pinchaque*.

Kartavtsev (2011) analyzed sequences of the *COI* gene from 20,731 vertebrate and invertebrate animal species. He estimated the average distance data for five different groups. He obtained $0.89\% \pm 0.16\%$ for populations within species, $3.78\% \pm 1.18\%$ for subspecies or semispecies, $11.06\% \pm 0.53\%$ for species within a genus; $16.60\% \pm 0.69\%$ for species from different genera within a family and $20.57\% \pm 0.40\%$ for species from separate families within an order. For this gene, the genetic differentiation between *T. terrestris* and “*T. kabomani*” was only 0.5%, clearly within the status of populations within species. Ascunce et al., (2003) and Collins and Dubach (2000) reported for Primates at the *COII* gene, an average genetic distance around 5.82% among species within a genus and around 2-4% for subspecies. For this gene, the genetic differentiation between *T. terrestris* and “*T. kabomani*” was only 1.3%, clearly within the status of populations within species. Bradley and Baker (2001) claimed, for the *Cyt-b* gene, that values $< 2\%$ would equal intra-specific variation, values between 2% and 11%

would merit additional study, and values >11% would be indicative of specific recognition. For this marker, the genetic differentiation between *T. terrestris* and “*T. kabomani*” was 1.8%, clearly within the status of intra-specific variation. The surprising question is the small genetic distances between *T. pinchaque* and *T. terrestris*, because these taxa have traditionally been considered full species. Thus, considering molecular genetic distances, *T. pinchaque*, should be considered a sub-species of *T. terrestris*. However, we consider *T. pinchaque* a full species because no natural or captivity hybridization has been reported due to reproductive barriers via stasipatric speciation with chromosomal changes (White, 1968, 1978).

The inaccurate result obtained by Cozzuol et al., (2013) was probably due to the fact that these authors only analyzed five samples of *T. pinchaque* at the *Cyt-b* gene and only one sample at the *Cyt-b* + *COI* + *COII* genes. Indeed, they only analyzed three samples at the *Cyt-b* gene, because two *T. pinchaque* samples were repeated due to that the two samples of *T. pinchaque* that M. Ruiz-García donated to the Cozzuol’s team were also donated by another scientist (that shared samples of the same animals with M. Ruiz-García) to B de Thoisy, who latter added his *T. pinchaque*’ results to those of Cozzuol et al., (2013). The very small *T. pinchaque* sample used by Cozzuol et al., (2013) probably did not represent all of the mitochondrial gene diversity of *T. pinchaque*. This contrasts with the larger *T. terrestris* sample containing animals from a very wide geographical area and thus retaining a major fraction of the mitochondrial gene diversity of this last species, and as the genetic distances between both *T. terrestris* and *T. pinchaque* were very small, by chance the no representative mitochondrial gene diversity of *T. pinchaque* of the small sample of Cozzuol et al., (2013) was nested within the gene diversity of *T. terrestris*. Nevertheless, as soon as we enlarged the *T. pinchaque* sample, collected from a wider sampling area, this phenomena disappeared.

Cozzuol et al., (2013) also provided alleged evidence of morphological and morphometric differences of “*T. kabomani*” from the remaining living and fossil South American tapir species. In this work, we provide molecular proofs that do not support the highly speculative and inconclusive conclusions of Cozzuol et al., (2013) that favor “*T. kabomani*.” We also provide several comments on the alleged morphological differences between “*T. kabomani*” and *T. terrestris*. In a recent study, Ruiz-García et al., (2015c) analyzed several *T. terrestris* populations throughout Northern Colombia and different areas of the Amazon basin in Colombia, Peru, Brazil and Bolivia from a craniometric perspective (around 160 skulls). Most of these populations showed significant statistical differences regarding the two areas of the skull where Cozzuol et al., (2013) found the greater divergence of “*T. kabomani*” with regard to *T. terrestris* (the position of the frontal-parietal suture related with the beginning of the sagittal crest and frontals broad and more inflated behind the nasals in “*T. kabomani*”). The significant differences of these skull from those studied by Ruiz-García et al., (2015c) within diverse *T. terrestris* populations were related to different ontogenetic patterns within each population as well as to the age composition of each population. The statistical differences were extreme among some of the seven *T. terrestris* populations studied for different morphometric traits (1- the Napo River area in the Northern Peruvian Amazon, 2- Yavari River and neighborhoods in the Amazonian border of Colombia, Brazil and Peru, 3- Sierra Nevada de Santa Marta in Northern Colombia, 4- Meta, 5- Caqueta, and 6- Vichada departments, all three in Colombia, and 7- the Mamore River in the Bolivian Amazon). However, we don’t claim that each one of these populations was a different tapir species, such as Cozzuol et al., (2013) claimed with “*T. kabomani*”.

Additionally, we show two other morphological proofs which don’t support the claims of Cozzuol et al., (2013). For example, supposedly *T. kabomani*,” with its lower sagittal crest and wider post-nasal exposition of frontals, is much smaller and has a darker color than the “typical” *T. terrestris*. In Figure 1A, we

show a tapir captured in the Amacayacu River (Colombian Amazon) with a “*T. kabomani*” mitochondrial haplotype. We also show, in Figure 1B, a “typical” morphological *T. terrestris* individual from Tena, at the upper Napo River in Ecuador. But, it had a “*T. kabomani*” haplotype. Both animals exhibited different morphotypes to that claimed by Cozzuol et al., (2013) for “*T. kabomani*”. For example, the Ecuadorian animal showed a considerable size and its color was brown. In contrast, as we show in Figure 10, in our travels to obtain tapir samples, we have found small-sized lowland tapirs. Figure 10A shows a pair of small-sized tapirs sampled in the Colombian Amazon, whereas Figure 10B shows a small tapir sampled in the Ecuadorian Amazon. We inspected the dentition of all three exemplars and determined them to be adults because each had at least two erupted molar. Nevertheless, no one showed “*T. kabomani*” haplotypes. The Colombian exemplars belonged to the Amazon II and III haplogroups, while the Ecuadorian individual belonged to the Amazon I haplogroup. Indeed, these animals were of a size smaller than the two individuals in the photo published by Cozzuol et al., (2013) and that were defined as “*T. kabomani*.” Additionally, and mistakenly, they affirmed the existence of photos of “*T. kabomani*” from Colombia. This was a mistake because we provided the authors with two Colombian samples that they claimed to be “*T. kabomani*.” Furthermore, we did not provide any photos of these animals. Most likely, they never asked for the morphology of these exemplars to verify a link between these “*T. kabomani*” haplotypes and the size and dark coat color of these individuals. Complementary, we have observed some lowland tapir adults with small sizes and certain bones deformations as if they were affected by malnutrition or some kind of genetic syndrome (for instance, small head and body but large feet).

(A)

Figure 10. (Continued).

(B)

Figure 10. Some *T. terrestris* adult exemplars with very small sizes but without “*T. kabomani*” mitochondrial haplotypes. Two small adult individuals from Leticia, Colombian Amazon (A); one small adult individual from Macas, Ecuadorian Amazon sampled by the first author (B).

Dobzhansky (1937), in his seminal book for the Neodarwinism synthesis, showed that in evolution the approaches should be of a population nature rather than a typological one. It is quite understandable that a paleontologist (such as is the first author of Cozzuol et al., 2013), working with the scarce material that provides the fossil record on most of the occasions, keeps a typological morphology vision of the species concept. Indeed, many paleontologists only accept a cladogenetic mechanism of speciation following the principle of the punctuated equilibrium theory (Eldredge and Gould, 1972; Gould and Eldredge, 1993). This means that the punctuated equilibrium can become tautological because paleontologists define fossil species on the basis of morphological change. So, it is a trivial problem to observe a strong correlation between speciation and morphological changes. However, population geneticists and evolutionary biologists (including Darwin) know the existence of rapid morphological evolution in a hypothetical ancestral form without speciation (phyletic transformation or anagenesis). Therefore, the existence of a certain morphological and morphometric skull variability in the lowland tapirs did not mean the real existence of different species. Furthermore, the “*T. kabomani*” case is a current living case, and not a paleontological one. With a living species, there are many other aspects to be analyzed in addition to changes in morphology before concluding on the existence of a new species. And, changes in morphology are the only aspects that can be detected in the fossil record. This project and other studies show that the samples sizes and the interpretation of mitochondrial and craniometric data by Cozzuol et al., (2013) are insufficient to define a new tapir species in the Amazon. Additionally and unfortunately, Cozzuol et al., (2013) did not provide sufficient geographical (they contrarily argue that “*T. kabomani*” is sympatrically extended by all the Amazon with *T. terrestris*),

ecological, ethological or reproductive (post and/or prezygote) barrier information to claim to “*T. kabomani*” as a new full species. This does not mean that other tapir species do not exist, but that the provided data are insufficient and misunderstood. In what-ever-the-case, nuclear DNA and especially comprehensive karyological studies (due to the possibility of stasipatric speciation; White, 1968, 1978) should be carried out before claiming the existence of new species of tapirs.

The Impact of the Pleistocene Changes on the Phylogeography of *T. pinchaque* and *T. terrestris*

The temporal split between the ancestors of *T. terrestris* and *T. pinchaque* occurred around 3.4 MYA. And, the beginning of the *T. terrestris* mitochondrial diversification was around 3.1-3.3 MYA. These times match up well with the end of the Pliocene and the beginning of the Pleistocene (2.6-1.8 MYA; Van der Hammen, 1992), which were extremely cold. The average temperature descended $4^{\circ}\text{C} \pm 2^{\circ}\text{C}$ and rainfall declined (500-1000 mm less than today) (Van der Hammen, 1992, 2001). The Pleistocene had 25 main glacial-interglacial cycles with climatic cycles changing every 20,000 Y for the first million years and thereafter every 100,000 Y. These climatic cycles had oscillations in temperature of 10°C at 2,500 m above sea level (masl). This first lowland tapir haplotype split (3.0-3.3 MYA) also coincided with the last formational phase of the Central Andes. The entire Andean chain between Cajamarca and Huancavelina was formed during this epoch by volcanic activity. The lagoons in Huancho (Northern Lima) and the bay in La Ventanilla Beach also formed during this time (León-Canales, 2007). The diverging process of the Amazon 0 haplogroup or “*T. kabomani*” and the haplotype diversification within *T. pinchaque* began around 1.3-1.2 MYA. This coincides with the Pre-Pastonian glacial period (1.3-0.8 MYA), which was extremely dry and cold. While the Buenos Aires province where mammalian fauna (*Categorius*, *Cyonasua*, *Clyomys*, etc) lived was basically tropical from 2-1.3 MYA, this climate later changed. This area was Patagonian Steppe-like around 1.3-0.8 MYA which agrees quite well with a dry and cold climate (Forasiepi et al., 2007). Examples of mammalian fauna living at this time were guanaco, *Lestodelphys* and *Lyncodon*. The diversification process within some of the *T. terrestris* haplogroups occurred around 0.5-0.3 MYA which showed that the same climatic events affected these lowland tapir haplogroups. This correlates to the beginning of the Kansas-Mindel glacial period, 0.4 MYA. Much of the haplotype proliferation we note in the haplogroups identified occurred around 0.2-0.06 MYA and in 0.03-0.01 MYA. This can be explained by the extreme climatic changes in these epochs. The last glacial-interglacial super-cycle began around 0.13-0.15 MYA (Würm. Wisconsin, Vistula, Gamblense). From 130,000 to 80,000 YA (Eemense period), the climate was hot, the precipitation greater, and there were extensive swampy forests of *Aliso*, *Vallea* and *Weinmannia* (Van der Hammen, 1992). But, an extremely cold climate (upper Pleniglacial period) began around 70,000 YA which could have had a fragmentation effect on the lowland tapir haplogroups. From 30,000 YA to 10,000 YA there were many periods of extreme dry and cold conditions. For example from 30,000 YA to 23,000 YA, there was a very cold period in Europe named Dryas I. During this period, the Fuquene Lagoon near the current Bogota (Colombia) dried (29,000 YA; Van der Hammen, 1992) and Mac Neish (1979). This determined changes in the soil acidity and the types of pollen at the Pikimachay Cove found within Peru which are related to the extreme cold 23,000 YA. Later, around 19,000-16,000 YA,

the Last Glacial Maximum (LGM or Dryer II) occurred, which had the most extensive distribution of snow and ice in the Central Andes within the last 200,000 YA. Metivier (1998) estimated that about 18,000 YA, the glacial extension in North and Central Andes was around 371,306 km², whereas it is currently around 3,220 km² (only 1% of the LGM). Also, there were intense cold periods from 14,000 YA to 10,000 YA (with alternating hot periods). Rodbell and Seltzer (2000) found moraines (the front of a glacial) up to 3,170 masl (12,000 YA) at the Cordillera Blanca (San Martin Department, Peru). Comparatively, today the glacial front is 4,600 masl. Also, Rodbell (1991) determined that the other areas of the Cordillera Blanca within the limits of the Departments of Huánuco and Ancash (17 glaciers) had snow lines at 4,200 masl, whereas today this limit is 500-900 m higher. Similarly, Seltzer (1987, 1990) determined the snow lines in the Huaytapallama, Junin and Huancavelina Departments (Peru) 10,950 YA to be 1,400 m lower than today. These climatic conditions could have caused the last lowland tapir haplotypes to diversify.

Several authors (Ab'Saber, 1982; Brown et al., 1974; Fjeldsä, 1994; Haffer, 1969, 1974, 1982, 1987, 1997, 2008; Prance, 1982, 1996; Prance and Lovejoy, 1985; Terborgh, 1992; Van der Hammen, 1975; Vanzolini, 1970, 1973, 1992; Vanzolini and Williams, 1970; Whitmore and Prance, 1987) claimed that these climatic events and subsequent dry/humid cycles created in the Amazon basin are the result of Milankovitch cycles. During the dry periods rainforest communities split into isolated refugia separated by savannah or arid pampas. This hypothesis was originally established for the Pleistocene, but later expanded to include the Miocene-Pliocene periods as well and it was named the Refugia Hypothesis. This hypothesis could explain the appearances of the different haplogroups within *T. terrestris*. During each dry period the haplogroups were formed, but later during the humid periods the tapirs migrated allowing its different haplogroups to diversify in different geographic areas. Along with this, the relationship between the original refugia areas was lost which helped create the geographical distribution of tapirs we see today. However, some Pleistocene refugia could have played an important role in the origins of the haplogroups. For example, the Amazon I and the "*T. kabomani*" haplogroups could have radiated from the Napo refugia (Northwestern Amazon), while the Amazon II and III haplogroups could have radiated from the Napo and Inambari refugia (Southwestern Amazon). The South haplogroup could have expanded from the Inambari or from the Rondonia refugia (between the Madeira and the Tapajos rivers), whilst the North haplogroup could have originated from the Bolivar refugia within the Guiana area. Another hypothesis, called the Recent Lake hypothesis (Klammer, 1984; Marroig and Cerqueira, 1997; Nores, 1999, 2004; Sombroek, 1966), could also support the formation of these lowland tapir haplogroups. This hypothesis claims that most of Amazonia was covered by a huge lake or lagoon during the Pliocene, and successively smaller portions of Amazonia were covered during a series of assumedly high sea level events during the Pleistocene. These created different islands and archipelagos within this Amazon lake. The different haplogroups could have been created on these islands. However, like the tapirs, who are exceptionally good swimmers, these haplogroups could have migrated throughout aquatic systems and expanded their original geographical areas. Therefore, both the Refugia and the Recent Lake hypotheses could support the existence of lowland tapir haplogroups. The significant and complex spatial structure found for the lowland tapirs in the Amazon basin by means of AIDA agrees quite well with both of these hypotheses.

Using Bayesian sky plot analyses, we determined the population changes over the last few thousand years for some of the lowland tapir haplogroups and geographical areas studied.

Amazon I suffered a population decline 5,500 YA coinciding with one of the dry periods of the Holocene after the Optimum Climaticum (OP). Following Rothlisberger (1987), around 6,300 YA, there was a significant increase in temperature especially in Southern South America as well as in the Central Andes, evidenced by O_{18} levels in Huascaran snow. This dry period around 5,500 YA was detected in the Amazon, Caqueta and lower Magdalena River basins as well as in Andean lagoons in Colombia and Peru (Thompson et al., 1995; Van der Hammen & Cleef, 1992; Van der Hammen, 2001). However, in the last 1,400 years, this haplogroup again increased. Amazon II and III revealed a population decrease 75,000 YA coinciding with the ending of the Eemian inter-glacial period and the beginning of the upper Pleniglacial period (Würm I; Van der Hammen, 1992). These two Amazon haplogroups began to again expand around 12,000 and 14,000 YA respectively. This could have been the result of finishing the coldest and driest period of the fourth Pleistocene glacial period, a period that is also related to the last major extinction period for mammals.

In contrast, North decreased 14,000 YA, agreeing with the massive extinction of mammals across the Earth including in South America. This corresponds with the Younger Dryas (Dryas III), typical of Northern Europe and Scandinavia (Clapperton, 1993). This means that the end of this extremely cold and dry period was not the same for all of South America and therefore the diverse haplogroups of tapirs were differentially affected. The Amazon's climate was not very affected by these drastic conditions—leading to an increase in some Amazon haplogroups. However, in Northern South America, the Younger Dryas was more drastic and the North haplogroup was negatively affected. Nevertheless, this lineage increased around 3,000 YA, just when the average temperature reached a value similar to what it is today (Van der Hammer, 1992). Finally, South suffered a population declination around 6,000 YA coinciding with the drier period between 7,000–5,500 YA that we commented on above.

When the data were analyzed by geographical area, only one region showed an important population declination in the last 5,000 years. This was the lowland tapir population of Northern Colombia and Northwestern Venezuela. This strong population decrease, detected by genetic methods, agrees quite well with the situation of this population, which was considered Critically Threatened in 2004 by the IUCN (Constantino et al., 2006).

In contrast to what was expected, in the Andes Mountains, the Pleistocene climatic changes did not create a phylogeographic structure in *T. pinchaque*. This is a conundrum because in other Andean mammals, such as the Pampas cat (*Leopardus pajeros*) (Cossíos et al., 2010; Ruiz-García et al., 2013), the Andean cat (*L. jacobita*) (Cossíos et al., 2012; Ruiz-García et al., 2013) or the spectacled bear (*Tremarctos ornatus*) (Ruiz-García, 2003, 2013; Ruiz-García et al., 2003, 2005), the phylogeographic structure for different kinds of molecular markers were significantly marked. This may support that the haplotype diversification within the current *T. pinchaque* occurred more recently than it did in *T. terrestris*. It's also possible that the gene flow capacity of *T. pinchaque* was relatively higher for this species in the Andean cordillera than for *T. terrestris* in the Amazon lowlands. The population expansion detected in the Ecuadorian *T. pinchaque* population could correlate with this last idea. If the mitochondrial diversification of *T. pinchaque* occurred much more recently than in *T. terrestris*, this could agree with an event of anagenesis, or phyletic evolution, with the original ancestor more related to *T. terrestris* than to *T. pinchaque*. *T. pinchaque* could have appeared via adaptation and exploitation of a new habitat within the Andean Highlands from a lineage, or population, of *T. terrestris*. It could have also appeared via stasipatric speciation. However, all of our phylogenetic trees do not agree with this perspective.

To complement these new mitochondrial results future studies should include sequences of HLA markers, autosomic and sexual chromosome introns and other nuclear DNA genes. Also, future studies focus on sequencing of tapir fossil remains may be helpful in our understanding of the evolution of the current mega-herbivores of South America.

ACKNOWLEDGMENTS

The authors are grateful for help and permissions from the Ecuadorian Ministerio del Ambiente, Ecofondo, Ecociencia, Zoological Foundation of Ecuador, Instituto para la Conservación y Capacitación Ambiental (ICCA), Tapir Specialist Groups-from Colombia and Ecuador, Andean Bear Foundation in USA and Ecuador and to the Von Humboldt Institute in Villa de Leyva (Colombia). Thanks are also given to Carlos Urgiles, Freddy Gallo, Leopoldo Gómez, Fabian Ascantá and Olimpo Gómez to help to obtain samples of *T. pinchaque* in Cuyuja and in Oyacachi (Ecuador). Also thanks to Dr. Diana Alvarez, Pablo Escobar-Armel, Luisa Fernanda Castellanos-Mora, the Peruvian Ministry of Environment, PRODUCE (Dirección Nacional de Extracción y Procesamiento Pesquero from Peru), Consejo Nacional del Ambiente and the Instituto Nacional de Recursos Naturales (INRENA) and to the Colección Boliviana de Fauna and CITES Bolivia (Dr. Julieta Vargas) for their respective help in obtaining *T. terrestris* samples during the last 18 years in Colombia, Perú and Bolivia. Also thanks go to the Ticuna, Yucuna, Yaguas, Witoto and Cocama Indian communities in the Colombian Amazon, Bora, Ocaina, Shipibo-Comibo, Capanahua, Angoteros, Orejón, Yaguas, Cocama, Kishuarana and Alama in the Peruvian Amazon, to the Sirionó, Canichana, Cayubaba and Chacobo in the Bolivian Amazon and Marubos, Matis, Mayoruna, Kanaimari, Kulina, Maku and Waimiri-Atroari communities in the Brazilian Amazon for helping to obtain *T. terrestris* samples.

ABSTRACT

Plants are responsible for a significant part of food supply for the entire world, and through agriculture they play an extremely important socio-economic role for the mankind. Therefore, the development of genetically improved crops becomes even more relevant for it aims at an everlasting enhancement of agronomic traits of interest. For many years, plant genetic improvement program has been based in empiric selection of the target traits; however, significant advances were obtained in the last years. Many tools, allowing crops to be improved with greater optimization of the time needed to reach the necessary modifications, are currently available. Regarding the methods used in the genetic improvement, molecular studies have been essential to identify which genes are important for each specific agronomic trait, such as those related to tolerance to abiotic stress. Such studies contribute not only to a better understanding of the endogenous defense mechanisms of plants at molecular level by which these organisms adapt when facing hostile conditions, but also contribute to the generation of stress-tolerant crops by genetic

engineering. These programs aim a significant productivity and sustainability that can be reached through soil preservation that is directly related to less necessity of farm inputs. Better adapted crop cultivars make it possible, as well as better use and decontamination of water resources. In this chapter we attempt at providing an overview regarding strategies that have been used for prospection of genes related to the response of plants to abiotic stress. The combination of biotechnological and bioinformatics tools used in the identification of stress-related genes and development of genetically engineered crops by silencing and/or over-expression of specific genes will be presented in this chapter. Emphasis will be given to the drought and salinity that represent a major part of abiotic stresses by which the plants are often exposed, leading to serious production losses in many important crops worldwide.

1. INTRODUCTION

The current human population of the entire world is estimated in seven billion people. Estimates also show an increasing to 7.5 billion of people by the year 2020 and to about 9 billion by 2050 (Lutz et al., 2001; Godfray et al., 2010). Therefore, to attend the nutritional requirements of human population in growing is necessary to enhance food productivity, including vegetable sources, which are also essential for animal feed. For example, estimates indicate that the world food grain production needs to be doubled by the year 2050 to attend the ever growing demands of the population (Tilman et al., 2002). Despite this need, some factors, such as climate changes and shrinking environmental resources, have significantly limited the agricultural production worldwide (Wang W et al., 2003). In addition, models of climate prediction indicate an increasing of 3–5°C of surface temperatures in the next 50–100 years, that will drastically affect the global agriculture (Solomon et al., 2007).

Adverse environmental conditions, which can potentially cause physiological limitations for plant growth and development, are known as stresses. Thus, plants are frequently exposed to a large range and number of environmental stresses, which when occurring simultaneously can cause severe consequences for these organisms.

Environmental stress, such as drought, salinity, cold and high temperature, are known as abiotic stresses. Among them, drought and salinity are common stress conditions that adversely affect crop production worldwide. For example, drought limits plant growth and development since can interfere in photosynthesis rates and soil nutrient availability. Likewise, salinity interferes with plant development, leading to physiological drought and ion toxicity (Krasensky and Jonak, 2012; Chaves et al., 2009). Otherwise, an improvement of abiotic stress tolerance might significantly increase the productivity of the most crops. Therefore, understanding the mechanisms of plant response to abiotic stress has been one of the most important priorities of studies in plant physiology, contributing for the development of stress-tolerant crops by genetic improvement programs that can be greatly advantageous in areas where the agriculture is limited by such stress.

For many years, the genetic improvement of crops has been performed by classical/conventional breeding programs that use the interbreeding of closely related individuals to produce enhanced crops with desirable agronomic traits. Classical breeding identifies traits of interest in parent lines and incorporates them into a new variety through crosses (or hybridization). This methodology is based on the genetic modification of wild species to create new altered cultivars (Doebley et al., 2006; Tang et al., 2010). Despite

conventional breeding has significantly contributed for development of new crop varieties, the pace to obtain new cultivars is relatively slow due to limitation of fertility barriers that allows only plants of the same, or closely related species for hybridization (Doebley et al., 2006). In addition, classical breeding requires a long period and several generations to select and evaluate useful genotypes, therefore, in some cases, this process can be limited to address global food security and attend the increasing requirements of food demands (Tester and Langridge, 2010). On the other hand, the advent of genetic engineering tools allowed the researchers to overcome some limitations found in classical breeding programs, where genes can only be exchanged between closely related species.

In 1970s, scientists were able to manipulate the genetic material at molecular level by DNA recombinant technology, also known as genetic engineering. This technology was the first step for isolation and manipulation of specific DNA sequences from any organism, allowing the transfer of genes within and across species boundaries (Cohen, 2013). With development of genetic engineering tools, significant advances in molecular biology were achieved in different research areas. Regarding investigations in plant molecular biology, one of the most important findings has been the understanding of molecular mechanisms by which plants recognize the stress signals from the environment to produce adaptive responses by expression of stress-inducible genes.

It is known that the complex process by which plant response to abiotic stress involves many genes and proteins playing specific functions in different biochemical and molecular pathways (Reis et al., 2012). Many drought-inducible genes are also induced by salt stress, suggesting the existence of similar mechanisms of stress responses. Stress-inducible genes coding for proteins can be classified into two main groups: (1) The first group comprises a large number of proteins with enzymatic or structural functions, such as enzymes involved in cellular detoxification process and synthesis of osmolytes, such as trehalose and proline, and other proteins with macromolecular protection, such as late embryogenesis abundant proteins, chaperones and mRNA binding proteins. (2) The second group involves a variety of regulatory proteins, such as transcription factors, protein kinases and receptor protein kinases, participating in diverse mechanisms of gene expression regulation (Agarwal et al., 2001).

Therefore, the identification of stress-induced genes contributes to understanding mechanism by which plants response and adapt themselves to abiotic stress, as well as molecular breeding of agriculturally important plants aiming the acquisition or increasing of stress tolerance. In this context, significant advances have been achieved by using the gene prospecting methodology, which covers the isolation and characterization of genes, including relevant *in vitro* and *in vivo* assays using molecular biology, bioinformatics and biotechnology tools. With the utilization of gene prospecting methodologies in many plant biology studies, several abiotic stress-inducible genes were isolated and their functions were precisely characterized in transgenic plants (Hirayama and Shinozaki, 2010).

In this chapter, we aimed to present some strategies that have used in prospecting of genes involved in response of plant to drought and salinity stresses. First, some genes coding for proteins playing roles in response to these stresses will be presented, taking into account their importance and potential application in molecular breeding programs. Later, some approaches for gene identification and genetic transformation of plants will be presented and discussed.

2. GENES CODING FOR PROTEINS INVOLVED IN RESPONSE TO DROUGHT AND SALINITY IN PLANTS

2.1. Basic Leucine Zipper Proteins and Absciscic Acid

Many physiological adaptations of plant to abiotic stress are under the control of the phytohormone abscisic acid (ABA) and involve specific activation of target genes that participate in the regulation of response to drought, salinity and low temperature (Cutler et al., 2010). It is known that cellular dehydration under water limited conditions induces an increase in endogenous ABA levels that trigger downstream target genes encoding signaling factors, metabolic enzymes, transcription factors, and others (Shinozaki and Shinozaki, 2006).

Transcription factors (TFs) are sequence-specific DNA-binding proteins able to activating and/or repressing transcription. TFs regulate transcription levels of target genes by mechanisms that often involve a whole cascade of signalling events determined by tissue type, developmental stage or environmental conditions (Wyrick and Young, 2002). Among environmental conditions, they represent a primary defense response to stimulus from abiotic stress (Riechmann et al., 2000). TFs can be classified in families according to their DNA-binding domain (Riechmann et al., 2000).

A single TF can control the expression of many target genes by specific binding to the *cis*-acting element within the promoters of target genes. This type of transcriptional regulatory system is termed *regulon* (Nakashima et al., 2009; Zahur et al., 2013). At least four different regulons can be identified, two ABA independent: (1) the CBF/DREB regulon, (2) the NAC (NAM, ATAF and CUC) and ZF-HD (zinc-finger homeodomain) regulon (Nakashima et al., 2009; Saibo et al., 2009); while two regulons are ABA dependent (3) the AREB/ABF (ABA-responsive element-binding protein/ ABA-binding factor), and (4) the MYC (myelocytomatosis oncogene)/MYB (myeloblastosis oncogene) (Saibo et al., 2009).

Many ABA-inducible genes contain a conserved *cis*-acting element named ABRE (ABA-responsive element; PyACGTGGC) in their promoter regions. Among TFs with ability to bind to ABRE, the basic leucine zipper (bZIP) proteins contain three functional regions involved in processes such as dimerization, DNA binding and transcriptional regulation (Bader and Vogt, 2006).

Studies have shown bZIP proteins involved in response to ABA, as well as response and tolerance to abiotic stress in many plant species. For example, Wang et al. (2011) reported increased transcript levels of bZIP in *Arabidopsis thaliana* plants under abiotic stresses, including drought and salinity. Other studies revealed bZIP proteins involved in the ABA signaling process in *Arabidopsis* that may, as a consequence, be classified as ABF or AREB (Choi et al., 2000; Uno et al., 2000). Also in *Arabidopsis*, an increased expression of bZIP genes promoted sensibility to ABA and changes in the expression of other genes related to stress, as well as improvement of the drought tolerance by transpiration reduction (Singh et al., 2002). In rice (*Oryza sativa*), the *OsbZIP23* gene conferred abscisic acid sensitivity and salinity and drought tolerance (Xiang et al., 2008). In another study also in rice, the *OsbZIP71* in presence of ABA significantly increased the tolerance to salinity and drought (Liu et al., 2014). In maize (*Zea mays*), two bZIPs with activity modulated by ABA and phosphorylation are involved in the expression of ABA inducible *rab28* gene, coding for a late embryogenesis abundant protein (Nieva et al., 2005). Since it is well known that late embryogenesis abundant

proteins are important in acquisition of tolerance to abiotic stress in many plants, they will be presented in next section. Another example of bZIP highly induced by ABA and abiotic stress comprises the soybean (*Glycine max*) *GmbZIP1*, which when over-expressed in transgenic *Arabidopsis* plants affected the expression of some ABA or stress-related genes involved in regulating stomatal closure in under ABA, drought and high salt stress conditions (Gao et al., 2011).

Therefore, the above cited studies confirm the importance of bZIP proteins in response to ABA and tolerance to abiotic stress, as well as their potential as candidate genes for molecular breeding programs aiming the development of genetically modified abiotic stress-tolerant crops.

2.2. Late Embryogenesis Abundant Proteins

Another class of proteins involved in abiotic stress response in plants comprises the late embryogenesis abundant (LEA) proteins. These proteins are ubiquitously distributed in the vegetal kingdom, and are found in vascular and nonvascular plants (Amara et al., 2014). LEA proteins are small molecular weight proteins ranging from 10 to 30 kDa (He and Fu, 1996) involved in acquisition of tolerance to drought, high temperature, salinity, cold, and freezing stress in many plants (Battaglia et al., 2008; Hundertmark and Hincha, 2008; Battaglia and Covarrubias, 2013).

Studies have shown that accumulation of LEA mRNAs is often observed in embryonic tissues during the final stages of the development of seeds exposed to desiccation (Hand et al., 2011). In addition, LEA gene expression is susceptible to considerable changes associated with the acquisition of tolerance to desiccation and development of seed germination capacity (Goldberg et al., 1989).

Several classifications have been used in order to group the LEA proteins, which in the most of case have their amino acid sequences deduced from cDNA and gene sequences. Among LEA classification methods, these proteins can be characterized according to the presence of natural motifs sequences (Dure et al., 1989), or a new version of the previous nomenclature proposed by Bateman et al. (2004), where is considered the presence of the Pfam motifs. It appears in contrast to the proposal of Wise (2003) which directs the analysis to the peptide profile of proteins (POPP analysis) by means of the current bioinformatics tools.

The most of LEA proteins are highly hydrophilic with no defined secondary structure in an hydrated stage (Amara et al., 2014), being consequently included into the group of intrinsically disordered proteins (Kushwaha et al., 2013). However, certain abiotic conditions, such as drought, can lead LEA proteins to a structured folding (Tunnacliffe and Wise, 2007). Wolkers et al. (2001) detected structural changes, such as conformations in α -helices or β -sheets, or both, in LEA proteins under dehydration. Likewise, Toller et al. (2007) observed structural changes in mitochondrial LEA of pea under drought conditions. Thus, this feature can be determinant to involvement of these proteins in such physiological processes (Olvera-Carrillo et al., 2011).

Due to the high hydrophilicity of LEA proteins, it has been suggested that they can act as hydration buffers by slowing down the rate of water loss (Garay-Arroyo et al., 2000), as proposed by Manfre et al. (2006) for AtEm6, an *Arabidopsis thaliana* LEA belonging to group 1. Also, it is known that these proteins can protect other proteins and/or component cellular

from aggregation or desiccation by retaining water, sequestration of ions, and acting as molecular chaperones (Kovacs et al., 2008).

The LEA roles in response to drought and salinity have been reported in many studies. For example, the accumulation of *MeLEA3* transcripts was increased in cassava (*Manihot esculenta*) leaves under *in vitro* salt stress (Costa et al., 2011). Wise (2003) reported that the tomato (*Solanum lycopersicum*) LE25 protein expressed in yeast favored growth of the transformants cells under salt stress in comparison to the control cells. On the other hand, bacteria cells expressing the recombinant LEA5 of rice were tolerant to drought in comparison to bacteria cells control (He et al., 2012). Also in bacteria cells, the recombinant PgLEA from *Pennisetum glaucum* conferred protection against salt stress (Reddy et al., 2012).

In addition to studies with heterologous expression of LEA proteins in yeast and bacteria, transgenic plants have also confirmed their roles in increasing of tolerance to abiotic stress. For example, the over-expression of a LEA gene in rice improved drought resistance under the field conditions (Xiao et al., 2007). Likewise, the *HVA1*, a LEA gene from barley (*Hordeum vulgare*) confers dehydration tolerance in transgenic rice via cell membrane protection (Babu et al., 2004).

Hence, with above cited studies, it is possible to conclude that the LEA genes are one of the most promising genes for molecular breeding programs aiming the production of crops tolerant to abiotic stresses.

2.3. Calcineurin B-like proteins

In plants, calcium is used as a second messenger in many signal transduction pathways, including responses to abiotic stresses (Sanders et al., 2002). Calcineurin B-like (CBL) proteins are calcium-binding proteins that function as signal sensor proteins able to detect changes in the concentration of cytosolic calcium and interact with target proteins (Luan et al., 2002; Sanders et al., 2002). CBL proteins can play roles in many calcium-dependent processes by interaction with a specific class of kinases named CBL-interacting protein kinases (CIPKs) (Luan et al., 2002; Batistic and Kudla, 2004). In addition, phosphorylation process by kinases is known as one of the major post-translational protein modifications playing important roles in many processes, including response against abiotic and biotic stress.

Studies have shown the involvement of CBL proteins and CIPKs in response and tolerance to drought and salinity. For example, Cheong et al. (2003) reported that CBL1 functions as a positive regulator of salt and drought responses and a negative regulator of cold response, since transgenic *Arabidopsis* plants overexpressing this gene enhanced tolerance to salt and drought but reduced tolerance to freezing. Later, the same group reported that the constitutive overexpression of the *CBL5* gene conferred osmotic or drought stress tolerance of *Arabidopsis* plants, that also showed highest resistance to salt during the primary development such as the seeds germination (Cheong et al., 2010). In poplar plants, the expression of *PeCBL6* and *PeCBL10* genes was induced by cold, drought, or high salinity, but not by ABA treatment. Likewise, transgenic *Arabidopsis* plants overexpressing *PeCBL6* or *PeCBL10* showed enhanced tolerance to high salinity, drought, and low temperature (Li D et al., 2013).

Mahajan et al. (2006) showed that the exposition of pea plants (*Pisum sativum*) to NaCl, cold and wounding co-ordinately up-regulated the expression of *PsCBL* and *PsCIPK* genes.

Also, these genes were coordinately stimulated in response to calcium and salicylic acid, however, drought and abscisic acid have no effect on their expression.

2.4. Trehalose-6-Phosphate Synthases and Phosphatases

Trehalose is a non-reducing disaccharide composed by two glucose molecules associated through anomeric carbons that plays an important role in metabolic regulation and abiotic stress tolerance in a variety of organisms, such as bacteria, fungi and some higher plants. The reaction of trehalose synthesis is catalyzed by two key enzymes: trehalose-6-phosphate synthase enzyme (TPS) and trehalose-6-phosphate phosphatase (TPP). TPS is codified by the *OtsA* gene in bacteria (Ström and Kaasen, 1993).

Trehalose naturally acts as a protective molecule against many types of stresses in different microorganisms (Eleutherio et al., 1993; Ström and Kassen, 1993). Likewise, many *in vitro* studies have confirmed the role of trehalose in the maintenance of biological structures (El-Bashiti et al., 2005) through stabilization of membrane or enzymes involved in dehydration defense in comparison to other carbohydrates (Paiva and Panek, 1996). Some mechanisms could explain the protective effects of trehalose, such as the replacement of water and chemical stability (Roser and Colaço, 1993). Therefore, the protection of structures on water removal can be accomplished by replacing water molecules in the hydration shell (Clegg, 1986).

Trehalose accumulation in plants can elevate the tolerance to salt and drought stress. Thus, due to above cited features and other peculiar characteristics, genes coding for enzymes involved in trehalose biosynthesis have been used in the genetic engineering of plants to improve abiotic stress tolerance (Serrano et al., 1999; Penna, 2003; Reis et al., 2012).

The initial studies that showed a yeast *TPS* gene promoting drought tolerance in plants, in this case tobacco plants (*Nicotiana tabacum*), were reported by Holmström et al. (1996). Since then, other studies have confirmed the importance of trehalose in tolerance to abiotic stress in many plants. Transgenic rice plants transformed with a bifunctional fusion enzyme (TPSP) of TPS and TPP from *Escherichia coli* showed increased trehalose accumulation and abiotic stress tolerance (Jang et al., 2003). Stiller et al. (2008) reported that potato plants (*Solanum tuberosum*) expressing the *TPS* gene of yeast showed an increased relative water content during the dry season. On the other hand, Suárez et al. (2008) reported the improvement of common bean (*Phaseolus vulgaris*) to drought tolerance and grain yield by over-expression of *TPS* gene in *Rhizobium* bacteria. In this study, common bean plants inoculated with *Rhizobium* bacteria over-expressing the *OtsA* gene showed increased biomass and water retention in comparison to control plants.

Regarding endogenous plant genes involved in trehalose synthesis, the over-expression of the *OsTPP1* gene conferred stress tolerance and caused the activation of other stress responsive genes in transgenic rice plants (Ge et al., 2008). Likewise, Li W et al. (2011) reported that transgenic rice plants over-expressing the *OsTPS1* gene showed improved tolerance to cold, high salinity and drought stress. These studies also revealed that in rice transgenic plants, trehalose and proline concentrations were increased and some stress-related genes were positively regulated by *OsTPS1* gene, including *WSI18* (water stress inducible protein), *RAB16C* (responsive to ABA), *HSP70* (Heat shock 70 KDa protein), and *ELIP* (early light inducible protein) (Li et al., 2011).

Besides trehalose, proline accumulation contributes also to increasing tolerance to abiotic stress in plants (Reis et al., 2012). Therefore, some studies about proline roles in protection against abiotic stress will be presented below.

2.5. Pyrroline-5-Carboxylate Synthases and Reductases

To adapt to drought conditions, plants need to reduce the water potential to ensure a positive flow of gradients from the soil to the roots and, therefore, plant cells need to reduce the osmotic potential through the accumulation of organic ions or solutes (Morgan, 1984). In this context, several studies have confirmed the importance of low-molecular weight metabolites and osmolytes, such as mannitol, trehalose, and proline, in tolerance to abiotic stress (Reis et al., 2012).

Proline participates in the osmotic adjustment of plants, that is characterized by the synthesis and accumulation of compatible osmolytes under drought (Kishor et al., 1995; Morgan, 1984). In plants, proline is synthesized in the cytosol and mitochondria from glutamate, which is converted to proline by two successive reductions catalyzed by pyrroline-5-carboxylate synthases (P5CS) and pyrroline-5-carboxylate reductases (P5CR) (Hare et al., 1999).

Studies show that the accumulations of products from synthesis and/or degradation of proline may increase the expression of several genes regulated by stresses in rice (Iyer and Caplan, 1998). As a result, high levels of cellular proline have been related to the prevention of protein denaturation, maintenance of structures and enzymatic activity (Samuel et al., 2000), as well as membrane protection against damage caused by the reactive oxygen species (ROS) during drought conditions and high light incidence (Hamilton and Heckathorn, 2001).

Many studies have confirmed the involvement of proline in response to abiotic stress. For example, the expression of *P5CS* gene in transgenic tobacco plants increased the production of proline and induced tolerance to osmotic stress in plants (Kishor et al., 1995). In cactus pear (*Opuntia streptacantha*), salt stress enhanced the expression of *P5CS* gene and induced proline accumulation (Silva-Ortega et al., 2008). In contrast, proline levels decreased when *P5CS* gene was silenced (Székely et al., 2008). Another study showed that *P5CS* gene was induced by drought stress, salt stress and ABA treatments, in contrast to *P5CR* gene (Yoshiba et al., 1995). Aroca et al. (2008) reported that in the absence of exogenous ABA, the *LsP5CS* gene was expressed only in plants under drought conditions. In soybean, the *GmP5CS* gene expression was increased in plants under drought conditions. In addition, the accumulation of *GmP5CS* transcripts was increased in plant nodes and proline levels were enhanced in plants submitted to conditions of low water potential (Porcel et al., 2004).

Wheat plants transformed with the *Vigna aconitifolia* *P5CS* gene showed tolerance to water deficit due to the mechanisms of proline protection against ROS produced by oxidative stress (Vendruscolo et al., 2007). In another study, the over-expression of moth bean *P5CS* gene in transgenic rice plants was driven separately with a constitutive and a stress-inducible promoter. This study revealed that stress-inducible expression of the *P5CS* transgene showed significant advantages in comparison to the constitutive expression, regarding the biomass production of transgenic rice plants cultivated under stress conditions (Su and Wu, 2004). Therefore, this study indicated that the use of an stress-inducible promoter driving the over-expression of *P5CS* gene can be a better option to development of transgenic plants with tolerance to abiotic stress.

2.6. Aquaporins

Drought and salinity interfere negatively in the plant-water relationship, since they cause absorption difficulties or substantial loss of H₂O molecules (Zhu et al., 2005). The rate of water flow across cellular membranes can be modulated by aquaporins, which are expressed in many cells and tissues. Aquaporins (AQPs) are proteins that enhance the water permeability of the membranes through differences between water potentials (Tyerman et al., 2002).

AQPs play a primary role in the formation of water channels that mediate and regulate the passive flux of molecules during plant growth and development processes, such as cell elongation, stomatal movement and responses against stress (Eisenbarth et al., 2005). AQPs have highly hydrophobic nature, with six membrane-spanning domains and molecular weights ranging from 26 to 34 kDa. Belonging to the family of major intrinsic proteins (MIPs), these membrane proteins have been localized in several kingdoms (Tyerman et al., 2002) and have 35 representatives isolated from *Arabidopsis* (Quigley et al., 2001), 31 genes located in corn (Chaumont et al., 2001), at least 14 obtained from *Mesembryanthemum crystallinum* (Tyerman et al., 1999), and 36 genes in wheat, *Triticum aestivum* (Forrest and Bhawe, 2008).

Regarding the AQPs classification, they are divided into four families considering the homology between amino acid sequences and subcellular protein location (Johanson et al., 2001). They are presented as follows: Plasma Membrane Intrinsic Proteins (PIPs) (Kammerloher et al., 1994), Tonoplast Intrinsic Proteins (TIPs) (Karlsson et al., 2000), NOD26-like Intrinsic Proteins (NIPs) (Weaver et al., 1991) and Small basic Intrinsic Proteins (SIPs) (Chaumont et al., 2001).

Since aquaporins are not only regulated in transcript levels, but also in regard to their activity (Martre et al., 2002). As reported by Gao et al. (2010), in wheat mutants to tolerance and sensitive to salinity submitted to salt stress, the *TaNIP* gene was regulated positively, however, the highest levels of expression were observed in mutant salt tolerant species. Also, studies by Mahdiah et al. (2008) supported the hypothesis that these genes are regulated by drought stress, despite a decreasing in *NtPIP1* and *NtPIP2* transcripts production in tobacco roots under exposure to drought, during the recovery period, the abundance of these transcripts was replenished. It shows the regulatory role of the aforesaid abiotic stress on gene expression of aquaporins. Moreover, the same study suggested that the transport of water to cell in roots is strongly inhibited in response to water stress. Thus, it can be inferred that the PIP water channels have participation in this process.

Plants under optimal water conditions showed a high *GmPIP2* gene expression. In opposition, plants submitted to stressful conditions showed significant reductions in gene expression (Porcel et al., 2006). Thus, inhibition of expression of certain genes must be understood as a strategy for reducing water molecules losses or restriction to water absorption into cells. It may also prevent water flow decrease in the tissues (Zhu et al., 2005), as observed in desert plants and beech seeds, in which aquaporins are inhibited possibly due to some of the reasons mentioned above (North et al., 2004). Also, *PIP* transcript levels were reduced in *Arabidopsis* plants under gradual lack of water on leaves (Alexandersson et al., 2005).

Results similar to those cited above have also been found by other researchers, such as Cui et al. (2008), who determined that the effects of bean *PIP1* expression in *Arabidopsis*, such as more elongated roots or abundant lateral roots, may secondarily assist in the acquisition of drought tolerance. On the other hand, when expressed in *Arabidopsis*, *PIP1* and *PIP2* genes of rice prevented the inhibition of roots growth, and were also involved in the improvement of salt

stress tolerance (Guo et al., 2006). Therefore, aquaporin genes showing both positive and negative regulation by drought and high salinity have been identified in *Arabidopsis*, rice and corn (Kawasaki et al., 2001; Seki et al., 2002; Wang H et al., 2003).

3. APPROACHES TO IDENTIFICATION OF GENES IN RESPONSE TO DROUGHT AND SALINITY

The above presented data ratify the significant advances in gene prospection in the search for better understanding about endogenous defense mechanisms of plants. However, there is still much information to be elucidated on this research field. In this sense, strategies related to the identification of genes in response to abiotic stresses constitute the first step for prospection of genes, so that the other steps can be implemented successfully. Among them, the subsequent *in vitro* functional analyzes at the transcript level or at the protein level by heterologous expression; and *in vivo* genetic transformation studies, as will be discussed later.

The high genomic complexity of plants requires effective tools and molecular biology strategies combined with bioinformatics to identification of genes. In addition, other eukaryotes characteristics, such as the presence of multiple introns, the alternative splicing, multiple copies of some genes and the presence of non-coding DNA regions among the genes, contribute also for requirement of multiple tools for identification of genes from plant genome. Such strategies are associated with the large number of sequences with available information in public databases, as well as computational programs, which can search these databases towards the identification of genes. It is worth noting that the nucleotide sequence analysis of a gene can be used to predict the amino acid sequence of the protein, contributing therefore to deduction of protein sequences aiming to find evidence that a potential gene is being expressed (transcription and subsequent translation of the corresponding mRNA molecule).

A computational procedure which is part of initial steps to determine the gene function consists of conducting a homology search, which is based on the comparison of DNA and/or proteins sequences from a determinated organism with other sequences from different organisms. The genes evolutionarily correlated are called *homologous*. In general, the identification of a particular gene (or gene prediction) is generated by automatic annotation, which identifies all biochemically active portions of the genome by sequence processing algorithms. The homologous genes found in different organisms that diverged from the common ancestral gene due to speciation are called *orthologous*. Similarly, the computational programs can search in a genome for the presence of *paralogs*, which are genes derived from an ancestral gene via gene duplication. The homologous genes, in general, have the same function or related functions. The sequence of a newly identified gene can be compared with a database seeking to find known domains. Whether the gene sequence encodes one or more domains whose functions were previously determined, the domain function can provide important information about the possible function of a new gene. So, after a function has been assigned to a given gene, it may provide clues, such as the function of another homologous gene (Cohen, 2004; Rhee et al., 2006).

A search program commonly used by the scientific community is the BLAST (basic local alignment search tool) (Altschul et al., 1990) that finds regions with local similarity among sequences. This program compares nucleotide or protein sequences obtained by sequencing

with the database sequences, and calculates the significance of the statistical combination. BLAST can be used to infer about evolutionary and functional relationships among sequences, as well as to help with the identification of gene family members (Cohen, 2004; Rhee et al., 2006).

The functions indicated by computational methods, such as searches for homologies, phylogenetic profiles, fusion proteins and neighborhood analysis do not define completely the function of a protein or a transcript. These methods provide inferences about possible functions, which can be confirmed by detailed analyzes of biochemistry and molecular biology, such as the generation of cDNA (complementary DNA) libraries for identification of differentially expressed genes. In this case, each obtained clone is called *cDNA clone*, and the entire collection of clones derived from an mRNA population constitutes a *cDNA library*. There are several methodologies of molecular biology that can be used to generate libraries with cDNA molecules. By action of a reverse transcriptase, such molecules are synthesized from mRNA molecules extracted from a tissue. After the synthesis of cDNA molecules by reverse transcription (RT), they are converted to double-stranded molecules by DNA polymerase and inserted into a plasmid or other vector by DNA ligase, followed by bacteria transformation, and they can therefore be stored for a long period with stability, unlike mRNA molecules, which are highly unstable (Birren et al., 1999; Sambrook and Russel, 2001; Alberts et al., 2008). Because it contains only sequences corresponding to the mature mRNA molecules (without the presence of introns), it is presumably that a cDNA library can contain only molecules having the identified genes sequences of interest that are differentially expressed under a certain condition. Since a cDNA library containing genes involved in response to stress was successfully synthesized, the screening of gene of interest can be performed by using specific primers or probes for isolation of the corresponding clone.

The isolation of a DNA molecule, followed by its insertion into a cloning vector and subsequent transformation of bacterial cell for its multiplication, constitutes an important stage in the gene prospection process, aiming its molecular characterization. Such studies have been conducted to genes in response to abiotic stress, such as drought and salinity, for which there are already pre-established studies; however, for certain species of socio-economic interest, more detailed studies are needed, for instance, genes that encode LEA proteins, RING-type zinc finger proteins and translationally controlled tumor proteins (Costa et al., 2011; Reis et al., 2012; Santa Brígida et al., 2014).

Next, will be presented some methodologies for prospecting genes regarding the identification of differentially expressed genes in response to abiotic stress in plants, such as those with up and down regulation in response to drought and salinity.

3.1. Differential Display Reverse Transcription-Polymerase Chain Reaction

As aforementioned, the study of gene detection can be carried out by analysis of correspondent RNA molecules. Such approach was initially performed using techniques related to the visualization of transcripts, where the intensity of cDNA bands detected by autoradiography allows inference about the expression level of a gene relative to a sample submitted to a determined condition.

In this context, the Differential Display Reverse Transcription-Polymerase Chain Reaction (DDRT-PCR) is a sensitive methodology for identification of genes, whose expression is

changed under a given situation. This methodology allows the identification of genes differentially expressed, with up or down regulated expression and the comparison of more than two mRNA populations (Liang and Pardee, 1992; Zhang et al., 1998), including plant genes involved in plant stress responses and physiological events (Cushman and Bohnert, 2000; Yamazaki and Saito, 2002). The laboratorial steps required for development of DDRT-PCR assays include: extraction and purification of total RNA, synthesis of cDNAs from mRNAs by using a reverse transcriptase enzyme, amplification of cDNAs by PCR, visualization of PCR products, reamplification and cloning of the differentially expressed PCR products, sequencing of the differential clones, and the obtention of full-length cDNAs of interest by synthesis of full-length cDNA libraries or RACE (Rapid Amplification of cDNA Ends) assays.

Several studies aiming to identify differentially expressed genes in response to abiotic stress in plants by using DDRT-PCR were successfully performed. For example, Liu and Baird (2003) detected thirteen cDNAs in response to drought and salinity in sunflower (*Helianthus annuus*), among them, some genes were up or down regulated according to each stress condition. Using DDRT-PCR, Li and Chen (2000) evaluated the differential accumulation of the S-adenosylmethionine decarboxylase (SAMDC) transcript in rice seedlings in response to salt and drought stresses. SAMDC is an enzyme related to synthesis of polyamines, which are involved in plant response to abiotic stress (Alcázar et al., 2006). Also in rice, Kong et al. (2003) identified a gene in response to salinity, with role in the alternative oxidase (AOX) pathway, which is related to several abiotic stresses in plants (Smith et al., 2009; Li C et al., 2013).

Torres et al. (2006) used the DDRT-qPCR (quantitative PCR in real time) and identified 16 cDNAs in beans, generating the identification of 4 genes in response to the water deficit related to several functions at the physiological level. In soybean, Martins et al. (2008) identified a differential cDNA coding for a phosphatidylinositol transfer protein, possibly related to response to drought and salinity by interaction with Ca^{2+} in the cytoplasm (Knight et al., 1997; Mueller-Roeber and Pical, 2002).

3.2. cDNA-Amplified Fragment Length Polymorphism

The cDNA-amplified fragment length polymorphism (cDNA-AFLP) is a methodology for gene identification, where a double-stranded cDNA is synthesized from mRNA molecules by a transcriptase reverse enzyme, followed by digestion with restriction enzymes, separation/visualization of DNA fragments on gels or autoradiography, generating unique patterns of gene expression and allowing the transcripts identification expressed in contrasting conditions (differential bands) (Bachem et al., 1996).

Since 1996, when the cDNA-AFLP was first reported, this methodology has been improved, comprising a useful tool for quantitative transcript profiling, as reported by Breyne et al. (2003), who proposed a adapted cDNA-AFLP methodology to perform genome-wide expression studies.

Therefore, in the last years, the cDNA-AFLP methodology has been used to the identification of differentially expressed genes in response to abiotic stress in many plant species with socio-economic importance. For example, using cDNA-AFLP, Campalans et al. (2001) identified genes that were highly expressed by dehydration in almond (*Prunus dulcis*), among them, genes encoding cysteine proteases with known roles in response to drought and salinity (Groten et al., 2006). In rice roots subjected to drought, Yang et al. (2003) detected in 28 genes

with unknown functions, 18 new genes in response to water deficit, and 60 genes with known functions, such as those related to signal transduction and the cell wall biogenesis. Gupta et al. (2013) also used the cDNA-AFLP to identify genes in response to drought in *Camellia sinensis*, an important medicinal and ornamental species. In this study, a functional ontology analysis ratified the detection of genes related to metabolism of carbohydrates and others in response to stress.

Using cDNA-AFLP, Umezawa et al. (2002) isolated genes in response to the high salinity in soybean. In addition, in combination with the RNA blot analysis, these authors observed that the differential expression of soybean genes occurred according to effects closely related to the salt stress in plants: osmotic effects (related to the limited water absorption by the rhizosphere due to the salinity) and ionic effects (unbalance or intracellular toxicity due to the ions excess).

Hmida-Sayari et al. (2005) used cDNA-AFLP to evaluated potato plants stressed by salinity, finding about 5000 bands, in which 154 were up-regulated and 120 were repressed by salt stress. Among them, these authors found putative genes for protein involved in cell wall structure and proline-rich proteins, amino acids commonly accumulated in plants subjected to salt stress and water deficit (Ashraf and Foolad, 2007).

3.3. Microarray

Methodological advances achieved by studies of gene expression include tools based on nucleic acid hybridization, such as the microarray. This methodology has been used in the analysis of genome of many plants and allows to analyze thousands of genes expression in a single assay. Also, microarrays enable integration of large datasets from several experiments (Lockhart and Winzeler, 2000; Gregory et al., 2008).

Microarray analysis requires a pre-determined numbers of oligonucleotide synthesized *in situ* or cDNA affixed (probes) in a solid surface (chip), which act as molecular detectors (Holloway et al., 2002). After RNA extraction from cells or tissues to be investigated, the transcripts are labeled with fluorescent dyes and hybridized with molecules affixed in the chip. Through the base pairing described by Watson and Crick between probe and target, is possible to evaluate a quantitative abundance measure of a particular mRNA sequence in the target population. The probes which correspond to a determined transcript hybridize to their respective complementary target. Thus, since the transcripts are labeled with fluorescent dyes, the light intensity can be used as a measure of gene expression. The comparison of hybridization patterns allows the identification of mRNA molecules which differ in abundance in two or more target samples (Murphy, 2002; Malone and Oliver, 2011). From the digital information captured, several analyses can be performed to the obtention of biological information of interest.

In *Arabidopsis thaliana*, Seki et al. (2001) evaluated the expression pattern of 1300 genes under drought and cold stresses using microarrays of full-length cDNAs. By RNA gel blot analysis, these authors detected 44 cDNAs induced by drought, being 6 new genes for DREAB1A/CBF3, a transcription factor which controls the gene expression induced by stress (Liu et al., 1998). Later, the same group reported the evaluation of expression of 7000 genes of *Arabidopsis* under drought, cold and high-salinity stresses using microarray. They evaluated the differential expression of 277 and 194 genes in response to drought and salinity, respectively, among them, genes that encode LEA proteins, heat shock proteins and enzymes

involved in the osmoprotectors synthesis (Seki et al., 2002). Also in *Arabidopsis*, the use of microarray in combination with qPCR, proved to be a tool quite useful to identify up or down regulation of gene expression under salt stress and genes simultaneously regulated by such stress and by ABA (Liu Y et al., 2013).

In rice, microarray assays were performed by Rabbani et al. (2003) aiming to evaluate the expression of genes in response to drought, high-salinity, ABA and cold. They used around 1700 independent cDNAs derived from three libraries related to these stresses previously prepared, and found 36, 43, 57 and 62 sequences induced by cold, high-salinity, drought and ABA, respectively. Also in rice, a microarray covering 36926 genes was used to analyze the gene expression profile to drought and salinity in three tissues, where it was detected strong specificity related to the expression profile detection in each tissue (Zhou et al., 2007).

The microarray allowed the identification of about 168 genes up-regulated under drought stress simultaneously in three cassava genotypes (Utsumi et al., 2012), as well as more than 1811 genes in wheat under salinity (Kawaura et al., 2006). The detection of transcripts expressed in chickpea (*Cicer arietinum*) for which the quantity depended on the kind and severity of stress, where more transcripts were expressed under high-salinity rather than by drought (Mantri et al., 2007). Curiously, among transcripts differentially expressed, these authors detected more repressed transcripts than induced (Mantri et al., 2007). In potato leaves submitted to salinity, Legay et al. (2009) verified that induction of various factors related to osmotic stress response occurs by ABA dependent or independent pathways and that there is a cross-talk between response to biotic and abiotic stresses, that is associated to several adaptation mechanisms involving proteins related to pathogenesis, heat shock proteins and late embryogenesis abundant proteins.

Chen et al. (2014) identified soybean genes encoding transcription factors HD-Zip (homeodomain-leucine-zipper), which were predicted to be related to drought and salinity. Likewise, in soybean plants subjected to drought, thousands of up and down-regulated genes were identified, among homologous encoding factors of transcription in *Arabidopsis thaliana*, DREB, NAC, AREB, and ZAT/STZ (Le et al., 2012).

3.4. Suppression Subtractive Hybridization

Another tool based on the nucleic acid hybridization is the subtractive hybridization. Its objective is to generate a cDNA library, which represents transcripts found in a specific tissue or organism, in determined moment or situation. In short, the first step is the cDNA synthesis from mRNA molecules extracted from cell populations or tissues to be compared. For example, a sample under abiotic stress conditions, and another sample under normal conditions. The cDNA population in which specific transcripts are found (i.e., the samples with cDNAs subjected to determined treatment) is called *Tester*, and the cDNA population (untreated) is called *Driver*. Then, tester and driver samples are hybridized and the resulting hybrids are removed. The unhybridized cDNAs, thereby, represent genes found in Tester and absent in Driver. Then, the differentially expressed cDNAs can be cloned, generating a subtractive cDNA library (Diatchenko et al., 1996; Lukyanov et al., 2007). Since subtractive cDNA libraries are constituted by partial cDNA sequences, methodologies aiming the isolation of full-length cDNAs, such as full-length cDNA library and RACE assays, are required for further characterization of differentially expressed genes.

Along the years, several subtractive hybridization techniques were developed, aiming a better optimization and effectiveness of this methodology, among them, the suppression subtractive hybridization (SSH), based on PCR suppression, in order to avoid the amplification of undesired DNA fragments. One of the main SSH advantages is the normalization of cDNAs abundance, allowing the identification of cDNAs encoded by genes which are rarely expressed (Diatchenko et al., 1996; Lukyanov et al., 2007).

In wheat, differentially expressed genes in response to drought were isolated by SSH generating a total of 300 expressed sequence tags (ESTs), that in combination with the microarray analysis, it was detected that 30% of the genes were up-regulated and 18% were significantly down-regulated under water deficit (Way et al., 2005).

The microarray and SSH approaches were also combined in study reported by Daldoul et al. (2010), where it was detected 7 vine (*Vitis vinifera*) cDNAs up-regulated by salt stress. With the same methodological combination, 201 non-redundant genes related to the high-salinity tolerance were isolated from tomato roots, among them, transcription factors and genes involved in the SOS (salt overly sensitive) pathway (Ouyang et al., 2007).

The SSH technique was also used to generate a cDNA library enriched with soybean transcripts differentially expressed in response to drought and, by Northern hybridization, 56 ESTs were validated as up-regulated genes in response to dehydration stress (Clement et al., 2008). Rodrigues et al. (2012) evaluated soybean cultivars with tolerance and susceptibility to drought by SSH, identifying differentially expressed genes during the initial response to water deficit in roots and leaves. In another study, Vidal et al. (2012) evaluated two soybean contrasting cultivars in terms of tolerance to drought and detected about two thousands genes up-regulated genes in both cultivars.

Montalvo-Hernández et al. (2008), in combination with the microarray analysis and Northern Blot, detected 18 beans cDNAs, among which, related to aquaporins, which, as highlighted above, are important water channel proteins and correlated to plants drought tolerance (Tyerman et al., 2002). Also in beans, Recchia et al. (2013) obtained 1120 ESTs, detecting sequences correspondent to proteins related to molecular aquaporins and chaperones, being verified the greatest expression of genes identified in the cultivar drought tolerant.

In drought analysis, the SSH was used to analyze the differential expression in sugarcane (*Saccharum officinarum*), being identified genes responsible for the sucrose-phosphate synthesis (Almeida et al., 2013). Ding et al. (2014) isolated and characterized genes in response to drought by SSH in peanut (*Arachis hypogaea*) involved mainly in the cell structure and metabolism, as well as some of them also associated to other stresses, such as high-salinity, cold, and stress to high temperatures. In addition, the analysis of seven genes by RT-PCR confirmed the genes differential expression in response to drought in the root (Ding et al., 2014).

In a study reported by Wu et al. (2005), SSH was used for evaluation of differentially expressed genes of a salt tolerant rice cultivar under NaCl treated, in comparison to non-treated plants. After a BLAST search in GenBank Databases, 31 cDNAs sequences were identified, among them, those involved in oxidative stress response, which is related to high salinity and other abiotic stresses (Wu et al., 2005).

3.5. Next Generation Sequencing

For a comprehensive understanding of genetic mechanisms involved development and response of plants to environmental stresses, a global gene expression analysis, associated with *in silico* approaches for sequencing analysis, has been fundamental. The sequencing process include a number of methods, which are broadly grouped from preparation of template to images supply and data analysis. The combination of specific protocols distinguish a technology from another and the kind of data produced by each platform.

By the wide variety of approaches adopted aiming large-scale studies of gene expression, bioinformatics tools associated to next generation sequencing (NGS) have significantly collaborated to studies of transcriptomes.. Although the first generation sequencing (Sanger) produces results to the biological researches, including the gene prospection related to plants resistance (Varshney et al., 2009; Recchia et al., 2013), more and more NGS platforms tend to be adopted, due to the higher generation of information combined with the higher results accuracy, covering the transcripts sequencing, as well as the genome resequencing or sequencing yet unknown (*de novo*).

The NGS platforms, available since 2005, promote the DNA sequencing providing information about millions of base pairs in a single run. Among them: the 454 System (Roche) based on the pyrosequencing; Solexa (Illumina) which, like the Sanger sequencing, is performed using DNA polymerase and nucleotide terminators labeled with different fluorophores and SOLiD System (Applied Biosystems), where the sequencing reaction is catalyzed by a DNA ligase, instead of a DNA polymerase (Mardis, 2008; Shendure and Ji, 2008).

The combination of NGS approaches with other methodologies has also been used as a strategy to reach the biological results of interest. The SAGE technology, serial analysis of gene expression, is based on high scale counting of specific regions (*tags*), obtained from a transcripts population. A latter connection (concatenation) of *tags* allows the efficient analysis of transcripts in a serial mode, by sequencing of multiple tags contained in a single clone (Velculescu et al., 1995; Chen et al., 2000). The methodological adaptations performed by Matsumura et al. (2005) to this method (*SuperSAGE*), in combination with the NGS, can contribute to the extent of gene identification involved in abiotic stress (Kido et al., 2013).

To identify genes in response to abiotic stresses, a sequencing focus has being the comparison of contrasting transcriptional profiles, as for instance, genotypes and distinct physiological conditions. In this context, the RNA-sequencing analysis (RNA-Seq) is the direct sequencing of transcripts by high-throughput sequencing technologies, where the mRNAs molecules are randomly fragmented and converted to cDNA fragments, which are subject to in-depth sequencing. The sequences are assembled and annotated using genome sequences as reference or *de novo* assemble. This methodology is very valuable, once it provides complete transcriptomes sequences, which can be used for various purposes, among them, the mRNAs quantitative characterization present in the transcriptome (Wang et al., 2009; Malone and Oliver, 2011).

Many studies aiming a global gene expression analysis of plants under abiotic stress have been reported. In maize, Xu et al. (2014) aimed the identification of candidate genes to drought tolerance and nsSNPs (non-synonymous single nucleotide polymorphisms), that interfere in the amino acid sequence, and can cause a modification in the structure and/or function of the protein. Then, these authors performed the resequencing of maize lines genome using the

Illumina Hiseq 2000 platform and further analysis of RNA-Seq, in combination with cluster grouping and CV (Common variants) analysis to identify nsSNPs and their associations with genes in response to drought. The authors identified a total of 524 nsSNPs associated with 271 candidate genes with different functions related to abiotic stresses, such as those related to the oxidative-reductive balance, commonly altered by the water stress.

In tomato, Wang et al. (2013) used the RNA-Seq to evaluate the gene expression in leaves sprayed with ABA, and detected various genes in response to drought and salinity. In soybean, the transcriptional profile of seedlings under salt and drought stress was analyzed by Fan et al. (2013) using the Illumina platform that detected 874 and 535 up-regulated genes under salt and drought stress in leaves, respectively, and 1822 and 1690 genes up-regulated under salt and drought stress in roots, respectively.

After treatment of mustard seedlings with high temperature, drought and salinity, Bhardwaj et al. (2014) identified 126 micro RNAs (miRNAs) by using the Illumina GA IIX sequencer. Li H et al. (2011) by using the Solexa sequencing technology, found 71 and 50 miRNAs differentially expressed in soybeans under drought and salinity, respectively. Kulcheski et al. (2011) compared soybean seedlings susceptible and tolerant to drought and detected several families of new miRNAs. In addition, RT-qPCR assays revealed that the majority of these miRNAs was up-regulated under stress in susceptible plants, and down-regulated in tolerant plants (Kulcheski et al., 2011), confirming the important roles of these molecules on the regulation of genes related to drought stress.

In common beans, His et al. (2014) detected 441 putative sequences of transcription factors related to the protection against high salinity by using the NGS. Wu et al. (2014) performed a large scale expression analysis in response to drought in common beans using RNA-Seq and validation by RT-PCR, where genes coding for transcription factors, such as WRKY, NAC and DREB, and proteins involved in pathways of phytohormones, such as auxin, gibberellins, and ethylene, were detected.

4. PLANT GENETIC TRANSFORMATION

After the identification of genes related to abiotic stress by using molecular approaches and *in silico* analysis, a more detailed functional characterization of these genes is required aiming an efficient prospection of genes of interest. In this context, the utilization of genetic transformation of plants is one of the most powerful approaches for functional studies of genes with potential for agriculture.

The plant genetic transformation allows the evaluation of the plant phenotype of transgenic plants achieved by the selection of successfully transformed cells (with the exogenous DNA integrated into the plant genome) and the plant regeneration (performed by tissue culture procedures aiming the formation of a whole plant from a single plant cell), requiring that the introduced gene into the plant genome (transgene) is properly expressed and transmitted across generations.

Aiming to understand how pre-identified genes are important at functional level, a useful strategy has been their over-expression in transgenic plants. Analysis based on gene silencing constitutes also an important tool to elucidate the functional relevance of certain genes that respond to abiotic stresses. Therefore, functional studies can be performed by over-expression

and/or silencing of genes with potential roles in response to abiotic stress, that were pre-identified by molecular and *in silico* methodologies.

In over-expression strategy, the coding region of gene to be expressed (transgene) is cloned into a vector under the control of a very strong promoter, which can be constitutive, inducible or tissue-specific, followed by introduction into the plant genome by genetic transformation methods. Despite constitutive promoters, such as the CaMV35S, can be very efficient in studies involving the over-expression of genes related to tolerance to abiotic stress, in some cases, stress-inducible promoters seem to comprise a better option in such studies. For example, Su and Wu (2004) reported that the over-expression of the *P5CS* gene, involved in synthesis of proline, in transgenic rice was more efficient when driven by a stress-inducible promoter than a constitutive promoter.

For silencing of genes, cassettes containing fragments of the gene of interest in sense and antisense orientations separated by an intron have been used (Zalewski et al., 2012). After plant transformation with cassettes, a double-stranded hairpin RNA (hpRNA) is formed and induces a silencing signal, which is short interfering RNA (siRNA). The formation of the hybrid molecule siRNA-mRNA of gene to be silenced induces the degradation process and post-transcriptional gene silencing (PTGS) (Chuang and Meyerowitz, 2000; Watson et al., 2005; Zalewski et al., 2012). This allows the understanding how the partial or total inhibition of a gene product can affect the plant phenotype.

The strategies for over-expression and silencing of genes can be performed by indirect and direct methods of plant genetic transformation, such as the *Agrobacterium* and biolistic that have been the most frequently used methods in molecular breeding programs of many important crops.

4.1. *Agrobacterium*-Mediated Genetic Transformation

Agrobacterium tumefaciens is a widespread naturally occurring soil bacterium, which shows the ability to introduce exogenous DNA into the plant cell. Since the first study reporting the use of *A. tumefaciens* in genetic transformation of tobacco plants by Herrera-Estrella (1983), the plant transformation mediated by *Agrobacterium* has become the most used method for the introduction of exogenous DNA into plant cells, followed by regeneration of transgenic plants. Therefore, along of years, the *Agrobacterium* method has allowed the introduction of genes conferring traits of interest for agriculture into many plants, including genes related to tolerance to abiotic stress (Cheong et al., 2003; Gao et al., 2011; Li D et al., 2013).

Agrobacterium genus has five species with the ability to penetrate into the plants, especially in dicotyledonous. Therefore, initially it was believed that *Agrobacterium* was able to infect only dicots, however, it was later established that some monocotyledonous plants can also be transformed using *Agrobacterium* method.

Among *Agrobacterium* species, the *A. tumefaciens* is the most used in studies of genetic transformation of plants. However, the *Agrobacterium rhizogenes*, a soil bacterium which stimulates in the host the proliferation of secondary roots from the infection point, can also be used for this purpose. Currently, the species *A. tumefaciens* and *A. rhizogenes* concentrate more than 600 host plant species. These bacteria contain a large plasmid, involved in development of tumor, named Ti (Tumor inducing) plasmid for *A. tumefaciens*, or Ri (Root inducing) plasmid, in the case of *A. rhizogenes*. During infection, the T-DNA (Transferred-DNA), a

mobile segment of Ti or Ri plasmid, is transferred to the plant cell nucleus and integrated into the plant chromosome. The T-DNA contains two types of genes: the oncogenic genes, encoding for enzymes involved in the synthesis of auxins and cytokinins and responsible for tumor formation; and the genes encoding for the synthesis of opines (de la Riva et al., 1998).

Along the years, many specific vectors for the *Agrobacterium*-mediated genetic transformation have been developed, taking into account that any exogenous DNA placed between the T-DNA borders can be transferred to plant cells. For example, the pCAMBIA vectors from the CAMBIA Institute (<http://www.cambia.org/>) comprised one of the most currently used vectors in studies of plant genetic transformation. In brief, in the transformation process using the *Agrobacterium*, a strain bacterium transformed with the vector containing the gene of interest is placed in contact with any explants, which have potential for plant regeneration, such as cotyledon, zygotic embryos, segments of young leaves, internodes and others. After contact with plant tissue, the *Agrobacterium* begins the stage of infection by transferring DNA and transforming the host genome. After the infection, the tissue culture techniques are required in order to regenerate a whole transformed plant containing the transgene. Selection agents and antibiotics are used to elimination of *Agrobacterium* bacteria and selection of transformed cells. Finally, molecular procedures are used to evaluate the transformed plants, such as DNA and RNA blot hybridization and PCR assays.

Advantages of using *Agrobacterium*-mediated transformation in comparison to other methods of transformation include a reduced copy number of transgene, and intact and stable integration of the transgene into the plant genome (Jones et al., 2005). In studies aiming the acquisition or increasing tolerance of plants to abiotic stresses, *Agrobacterium* method showed high efficiency and wide applicability, with a high potential for integration of genes in plants to monitor the phenotype and perform functional studies, in both dicots and monocots plants. For example, Xiang et al. (2008) obtained transgenic rice plants with tolerance to drought and high-salinity stresses by over-expression of the *OsbZIP23* gene using the *Agrobacterium* method. Likewise, Zhou et al. (2012) produced transgenic tobacco plants over-expressing the *TaAQP7* gene (aquaporin) with increased resistance to drought. In millet plants (*Setaria italica*), the over-expression of the gene *SiLEA14* by *Agrobacterium*-mediated genetic transformation provided a high tolerance to drought and salinity (Wang et al., 2014).

4.2. Biolistic-Mediated Genetic Transformation

The genetic transformation of plants may also be performed by direct methods, among them, the biolistic has shown high efficiency and broad applicability in plant molecular breeding aiming the resistance to abiotic stresses, our goal in this chapter.

The biolistic, also known as microparticle bombardment, was firstly reported by Sanford et al. (1987), who invented an air pistol modified to fire dense tungsten particles used in delivering of substances into cells and tissues. Since then, the ‘biolistic apparatus’ has been modified and improved, and currently many models of microparticle bombardment apparatus are commercially available for scientific community. Many of them use a helium pulse, at high pressure, to accelerate gold or tungsten micro-particles containing the DNA molecule to be incorporated into the target tissue or cells. Then, the accelerated particles penetrate both the cell wall and membranes, and the DNA separates from the metal and can be integrated into the genetic material inside the nucleus.

Among advantages of plant genetic transformation mediated by biolistic, it is useful to practically all species of plants, in special the monocots. Then, with the biolistic is possible to maximize the gene transfer to a variety of cells, tissues and plant species. Also, the biolistic is considered a rapid and very simple procedure, being very useful in the direct transformation of totipotent tissues, such as pollen, embryos, meristems and morphogenic cell cultures. In addition, the biolistic process is suitable for organelle transformation (Sanford, 1990), that is particularly very appreciable, since the genetic transformation of organelles has emerged as a powerful tool in genetic engineering of plants in the last years. The expression of exogenous genes in organelles, such as chloroplasts, offers several advantages over expression in the nucleus, such as high-level expression and no transfer of genes expressed in the plastome through pollination to weedy or wild relatives of the transgenic crop (Wani et al., 2010). On the other hand, the use of biolistic requires the acquisition of special instrumentation (biolistic apparatus) (Sanford, 1990). Also, for performing of studies using biolistic, frequently, is necessary the development or optimization of specific protocols for genetic transformation, taking into account various physical and biological factors for the success of the method, such as particle size to be used, the speed employed on the particle, the type of apparatus to be used, precipitation method, plant species, explant type, among other issues (Sanford, 1990).

Many authors have reported the efficient use of the biolistic in functional studies of genes potentially related to plant response to abiotic stress. For example, Xu et al. (1996) reported the generation of transgenic rice plants with resistance to drought and salinity by expression of LEA gene via biolistic-mediated genetic transformation. Likewise, Ganguly et al. (2012) reported the over-expression of *Rab16A* gene (group 2 LEA protein) in transgenic rice plants with increased salt tolerance.

A valuable strategy for studies involving the plant genetic transformation is regarding the comparison of efficiency between different methods of transformation. Then, a gene of interest is transformed by using different transformation methods and their results are comparatively evaluated. In this context, the suitability of the *Agrobacterium* method over the biolistic has been shown by some studies. For example, Zalewski et al. (2012) reported that the *Agrobacterium* method was more efficient in silencing of the developmentally regulated *HvCKX2* gene in barley in comparison to the biolistic, which showed low productivity and disturbances in plant development.

Regarding to the use of such comparative study using genes involved in tolerance to abiotic stress, Shou et al. (2004a) detected that the expression of the *Nicotiana* protein kinase (*NPK1*) gene enhanced drought tolerance in transgenic maize. Also, the same authors reported that maize transgenic plants over-expressing the *NPK1* gene by *Agrobacterium*-mediated genetic transformation showed lower transgene copies, and higher and more stable gene expression than transgenic plants generated by biolistic. It is known that the introduction of a reduced copy number of transgene comprises one of the advantages of *Agrobacterium* method, since the integration of high numbers of transgene copies often leads to transgene silencing (Shou et al., 2004b; Travella et al., 2005).

CONCLUSION

The several topics discussed in this chapter confirm the importance of gene prospection studies, deeply related to the scientific efforts in the search for crop genetic improvement to overcome the abiotic stresses. Strategies for molecular breeding of agriculturally important plants aiming the acquisition or increasing of tolerance to abiotic stress include the over-expression and/or silencing of specific genes. Despite the identification of several genes coding for proteins related to response to abiotic stress, such as drought and salinity, this prospection still has a long way to go, not only to continue identifying more genes, which have their expression regulated by stress, but also to unravel with more detail the physiological and molecular roles of genes and proteins already identified. Additional studies involving functional analysis and identification of genes essential for abiotic resistance, seeking to better understand the optimal level of expression of various genes so that there is optimal interaction of their gene products compatible with the generation of well adapted plants, thereby overcoming the adverse conditions at the field level.

ABSTRACT

Proteinuria is the hallmark of diabetic nephropathy (DN) and vastly increases the incidence of cardio-vascular disease and mortality. Traditional Chinese Medicine (TCM) has been used for diabetes and its complications for thousands of years and appears to be promising in the treatment of proteinuria in DN patients. Clinical trials evaluating TCM for proteinuria, either used as a monotherapy or in combination with western medicine, has produced positive results. Although a large number of clinical studies have been conducted, the clinical evidence with regard to TCM for proteinuria in patients with DN remains inconclusive. The recent progression of evidence will be introduced in this chapter. Current basic research has disclosed that TCM might affect a variety of genes regarding DN

etiology. This chapter will analyze recent achievements in this area and address the issue of the association between clinical evidence and the genetic effects of TCM.

INTRODUCTION

Diabetic nephropathy (DN) is one of the micro-vascular complications of diabetes mellitus. It is characterized by proteinuria and glomerulosclerosis [1]. Proteinuria not only marks the occurrence of DN, but also vastly increases the incidence of cardio-vascular disease and mortality. Many factors contribute to the etiology of DN, such as glomerular hyperfiltration, involvement of cytokines, increase of glycosylated end products, activation of sorbitol and protein kinase C pathways, and susceptibility of genes, etc. In the past few decades, Chinese medical experts have disclosed a number of genetic variants which may be associated with diabetic nephropathy in the Chinese population. Some of the recent findings are shown in Table 1.

Table 1. Genetic variants which have been investigated in Chinese ethnic populations with diabetic nephropathy

Genetic variants	Results associated with DN	Studies	Cases/ Controls (N)	Ethnic population	Region

This chapter primarily focuses on the association between the clinical evidence of Traditional Chinese Medicine (TCM) for the treatment of proteinuria in patients with DN and the genetic effects of TCM on DN. The chapter examines the following research issues: 1) Clinical evidence of TCM for proteinuria in DN patients; 2) The effects of TCM on DN at the genetic level; 3) The association between the clinical evidence and the genetic effects of TCM. This chapter's discussion will analyze the research and answer the following questions:

Clinical evidence of TCM for proteinuria in DN patients

1. What are the results of randomized controlled trials (RCTs) studying the anti-proteinuric effects of TCM in patients with diabetic nephropathy?
2. What do the systematic reviews and meta-analyses report in this area?
3. What are the limitations with respect to this clinical evidence?

The effects of TCM on DN at the genetic level

1. What are the effects of TCM on DN at the genetic level in animal experiments?
2. What are the effects of TCM on DN at the genetic level in humans?

The association between the clinical evidence and the genetic effects of TCM

1. What is the association?
2. How to relate them?

CLINICAL EVIDENCE OF TCM FOR PROTEINURIA IN DN PATIENTS

What Are the Results of Randomized Controlled Trials Studying the Anti-Proteinuric Effects of TCM in Patients with DN?

Conventional western medicine has developed common medications for the treatment of proteinuria, i.e., angiotensin-converting enzyme inhibitor (ACEI) and angiotensin receptor blocker (ARB). Unlike conventional western medicine, the TCM community can use not only ACEIs or ARBs but also TCM for the management of DN in China. The body of research literature for RCTs evaluating TCM for DN is rapidly increasing. Most of these RCTs measured the changes of urinary albumin excretion (UAE) levels and evaluated the anti-proteinuric effects of TCM in DN patients; consequently, this has become a topical area of research [70,71]. A large number of TCM has been assessed in this area and numerous clinical trials have been reported [72]. It is beyond the scope of the present analysis to elaborate on the multitude of individual research. Instead, our method will be to utilize the PubMed international medical research engine to present the RCT citations.

TCM as a Monotherapy

TCM Extract

Tripterygium Glycoside

Studies where TCM was used as a monotherapy usually produced positive results [73]. Tripterygium Glycoside is extracted from the Chinese Medicinal herb, *Radix Tripterygii Wilfordii*. It has immunosuppressive and anti-inflammatory effects [74,75] and some animal experiments demonstrated that it could reduce UAE by protecting podocytes [76,77]. Chinese military medical experts conducted clinical trials to assess its efficacy and safety in the treatment of DN. The Chinese academician, Liu ZH and his team, published an article in 2010, reporting a six month RCT where Tripterygium Glycoside was used as a monotherapy in the treatment of DN [78]. 65 patients whose $\text{UAE} \geq 2.5 \text{ g/24h}$ and $\text{SCr} < 265.2 \text{ mol/L}$ were included and they were randomly assigned into two groups: Tripterygium Glycoside group (34 S) and valsartan group (31 S). Both groups had four patients lost at follow-up and one patient withdrew. The reduction of UAE was EXTREMELY significant in the Tripterygium Glycoside group: compared with the baseline values, there was a 32.9% reduction at month 1; a 38.8% reduction at month 3; and a 34.3% reduction at month 6. However, the reduction in the valsartan group was not significant: there was a 1.05% reduction at month 1; 10.1% at month 3; and -11.7% at month 6. The authors analyzed the lack of efficacy in the valsartan group, stating it might be associated with the dose of valsartan (160 mg/d), a high value of inclusion criteria on proteinuria ($>2.5 \text{ g/24h}$) and the short trial period (six months). However, it is obvious that the efficacy of Tripterygium Glycoside is superior to valsartan. The reported adverse events of Tripterygium Glycoside were as follows: gastrointestinal adverse reaction (1 S, 2.94%); abnormal liver function (3 S, 8.82%); reduction of white blood cell (1 S, 2.94%); hyperkalemia (8 S, 23.53%); $\text{K}^+ > 6.0 \text{ mmol/L}$ (3 S, 8.82%). The reported adverse events of valsartan were: photosensitive dermatitis (1S, 3.22%); hyperkalemia (10 S, 32.2%); $\text{K}^+ > 6.0 \text{ mmol/L}$ (2 S, 6.45%); and serum creatinine doubling (1 S, 3.22%). The three subjects who had abnormal liver function recovered when the dose of Tripterygium Glycoside was reduced to 60 mg/d; they did not withdraw from the trial. The incidence of hyperkalemia was high because many subjects had renal insufficiency, but symptomatic treatment could successfully manage it. The authors concluded that Tripterygium Glycoside is a safe drug whose efficacy is superior to ARB in the treatment of DN.

Formulae

Tangjiang Shenkang (TJSK)

Although clinical trials of poor methodology continue to devitalize legitimate TCM research, RCTs of higher methodology are emerging. Ma et al. (2011) carried out a randomized placebo controlled double blind trial to evaluate the efficacy and safety of Tangjiang Shenkang (TJSK) granule in the treatment of DN [79]. The methodology of using a well-designed RCT was able to correctly identify the exact efficacy of TCM because it minimizes the risk of bias. This multi-center trial included 194 patients with DN at Mogensen stage III and stage IV and the intervention course was eight weeks. The primary outcome measure of this RCT was the change in UAE. There were three arms, i.e., a placebo group (60 S), low dose group (64 S), and

high dose group (62 S). The baseline values of UAE among the three arms were similar, and the values of UAE after eight weeks significantly changed: both the high dose and the low dose group were lower than the placebo group ($P < 0.01$), but there was no significant difference between the low dose and the high dose group ($P > 0.05$). Two subjects in the high dose group and one S in the low dose group had slight abdominal pain and diarrhea. The adverse events disappeared when TCM was terminated. The authors concluded that TJSK is effective for the management of proteinuria in DN patients. TCM is usually seen as a medicine based on experience, but a well-designed RCT could make it evidence-based.

Qiyao Xiaoke (QYXK)

Ni Qing and his co-workers (2013) carried out a multi-center randomized double blind placebo-controlled trial to assess the clinical effects of Qiyao Xiaoke (QYXK) capsule in the treatment of early DN [80]. The trial included DN patients whose 24-h UAE between 30 mg/24h to 300 mg/24h and 24-h proteinuria < 0.5 g. The trial lasted 12 weeks and the 24-h UAE and proteinuria were measured. 150 patients were included and 101 S were assigned to the TCM treatment group and 45 to the control group. Four S did not complete the trial. The statistical analysis based on the per-protocol set showed that the QYXK capsule could significantly improve proteinuria. The 24-h UAE decreased from 219.74 ± 68.36 to 109.52 ± 56.43 in the TCM treatment group; meanwhile, the values also decreased from 223.95 ± 70.67 to 142.67 ± 73.45 in the placebo control group. The authors reported the efficacy of TCM was superior to that of the placebo based on a paired t test. In general, this trial has optimal methodological quality, but it is a pity that it did not use intention-to-treat (ITT) analysis because the statistical analysis was based on the per-protocol set.

Combination Therapy with TCM and Western Medicine

Astragalus

The clinical trials where combination therapy with TCM and western medicine were used for the management of DN also reported positive results in reducing UAE. Astragalus is a famous Chinese medicinal herb in the treatment of DN and in China is usually used in injection form. Liu YH et al. (2005) carried out a RCT to assess the clinical efficacy of combination therapy with astragalus and captopril in the treatment of early DN [81]. 69 S were randomly assigned to three groups: a captopril group (23 S); astragalus group (23 S); and a combination group (23 S). The UAER value of the captopril group decreased from 140 ± 37.8 $\mu\text{g}/\text{min}$ to 111.2 ± 28.6 $\mu\text{g}/\text{min}$; that of the astragalus group decreased from 135.0 ± 33.4 $\mu\text{g}/\text{min}$ to 110.9 ± 21.5 $\mu\text{g}/\text{min}$; and that of the combination therapy group decreased from 138.8 ± 27.8 $\mu\text{g}/\text{min}$ to 96.2 ± 18.1 $\mu\text{g}/\text{min}$. The adverse events were cough (captopril group: 5 S and combination therapy group: 4 S); elevation in serum creatinine (captopril group: 1 S); and hyperkalemia (captopril group: 1 S). There was no adverse event in the astragalus injection group. The authors concluded that the combination therapy with astragalus injection and captopril could significantly reduce the UAER in patients with early DN.

Other TCM

Tu Xiang et al. (2014) reviewed the current literature concerning combination therapy with TCM and ACEI/ARB in the treatment of DN [82]. The authors searched three major Chinese

databases and PubMed. Rigorous inclusion criteria was applied and eventually only eight RCTs were included. The present chapter summarizes some interesting findings: three observational RCTs reported that TCM could provide benefits on proteinuria and renal function in addition to conventional western medicine (CWM); three observational RCTs reported that TCM provided added benefits on proteinuria to CWM; and two observational RCTs reported that TCM does not provide additional benefits on proteinuria or renal function to CWM. The authors fully discussed current progress in this area and stated – “Although the present review could provide an overall impression that TCM has some clinical effect, especially, when combined with ACEI/ARBs, it is really difficult to provide a clear picture about individual TCM or TCM products”.

What Do the Systematic Reviews and Meta-Analyses Report in This Area?

In sharp contrast to the positive results reported by RCTs, all systematic reviews and meta-analyses could not draw convincing conclusions. A closer look reveals some peculiar results.

TCM Extract

Breviscapine

The Chinese Journal of Evidence-based Medicine (CJEBM) published a series of systematic reviews to evaluate the efficacy and safety of TCM for the management of DN. Shi JY et al. (2009) published a systematic review which aimed to assess the efficacy and safety of breviscapine for DN, where the UAE levels were one of the primary outcome measures [83]. 33 original studies met the inclusion criteria and 2322 DN patients were eventually included (1214 S in the breviscapine treatment group and 1108 S in the control group). Breviscapine was administered intravenously. The results of meta-analyses demonstrated that breviscapine could significantly reduce the UAE level, compared with the controls, but the methodological quality of the 33 observational studies were classified as C grade (indicating poor methodology). The funnel plot was asymmetric, which indicates that negative results might not be published. The authors stated “no significant adverse events were reported” and they concluded “breviscapine shows some effects and is relatively safe on diabetic nephropathy”. Most importantly, the authors realized that “the evidence is not strong enough”.

Tripterygium Glycoside

Wu WH et al. (2010) carried out a systematic review to evaluate the efficacy and safety of Tripterygium Glycoside for DN [84]. 12 Chinese RCTs were included and none reported the allocation concealment, blindness, drop-out or attrition at follow-up, or ITT analysis. Obviously, methodology of most included studies was poor. The results of meta-analysis showed that Tripterygium Glycoside was superior to controls in reducing 24-h proteinuria [WMD=-0.49, 95%CI (-0.63, -0.34)] and 24-h UAE [WMD=-148.75, 95%CI (-238.01, -59.48)]. However, there was no sound evidence, and no reliable conclusions.

Ligustrazine

Wang B et al. (2012) published a meta-analysis to assess the clinical effect of ligustrazine, extracted from Chuanxiong (*Ligusticum chuanxiong* Hort), on diabetic nephropathy [85]. 25

RCTs involving 1645 patients were included. Although the authors concluded that “Ligustrazine injection has a significant therapeutic effect on ... reducing urine protein (24 h urine protein, urine micro albumin and urinary albumin excretion rate [UAER]) in DN patients”, the quality assessment from the Center for Reviews and Dissemination of the University of York arrived at a more cautionary statement – “Due to potential limitations in the included evidence and in the reporting and conduct of the review, this conclusion may not be reliable” [86].

Ginkgo Biloba Extract

Zhang L and his colleagues (2013) reported a systematic review and meta-analysis to evaluate the effectiveness and safety of a Ginkgo biloba extract for patients with early DN [87]. UAER was the primary outcome measure. 16 RCTs involving 1099 participants were included. Six trials elaborated randomization methods and none used blinding in the design. Although the methodological quality of observational studies were sub-optimal, the results of meta-analyses were in favor of Ginkgo biloba extract. Comparing the Ginkgo biloba extract plus conventional treatment versus conventional treatment only: 1) for the patients whose baseline UAER >150 µg/min, UAER decreased with an overall effect size of 74.52 µg/min (95% CI, from 63.89 to 85.15, $P < 0.00001$); 2) for the patients whose baseline UAER <100 µg/min, UAER decreased with an overall effect size of 23.88 µg/min (95% CI, from 22.58 to 25.18, $P < 0.00001$). Comparing the Ginkgo biloba extract combined with ACEI/ARB versus ACEI/ARB alone, UAER decreased with an overall effect size of 27.95 µg/min (95% CI, from 22.06 to 33.84, $P < 0.00001$). The authors therefore concluded that Ginkgo biloba extract is a “valuable drug” for DN, especially for those have high baseline UAER levels.

Puerarin

Wu Wei and his co-workers (2013) conducted a meta-analysis and reported that puerarin could significantly reduce UAE levels in patients with micro-albuminuria, no matter the dose low, middle or high [88]. Seven included studies scored 1 point and two studies scored two points, which means the results of meta-analysis were not sound – being based on poor methodological clinical trials.

Individual Traditional Chinese Medicinal Herb

Astragalus

There was only one individualized study. Li M et al. (2011) published a meta-analysis to evaluate the efficacy of astragalus in the treatment of DN [89]. 25 clinical trials involving 1804 patients were included. The results of meta-analysis showed that astragalus could significantly improve proteinuria compared with the controls. The authors believe that the results were encouraging. Few individualized herb meta-analysis has been published and astragalus is obviously the most extensively studied individual TCM herb.

Formulae

Xuezhikang

A systematic review was published in CJEBM (2009) which aimed to evaluate the efficacy and safety of Xuezhikang for DN [90]. Nine Chinese RCTs were included and they were classified as B grade in methodology indicating moderate bias. Xuezhikang was superior to routine western medicine in reducing 24-h proteinuria [WMD=-0.87, 95%CI (-1.34, -0.41)] and UAER [WMD=-65.46, 95%CI (-68.87, -62.12)]. It is also interesting that the results of meta-analysis showed Xuezhikang was similar to routine western medicine in improving serum creatinine. These results are in line with reports (pending publication) by Tu Xiang et al. [82] – the benefits of TCM on renal function parameters were not always consistent.

Danhong

Zhang MX et al. (2009) published a systematic review in the CJEBM to evaluate Danhong injection for DN [91]. Ten original studies involving 736 subjects were included. The dose of Danhong injection ranged from 20 ml/d – 40 ml/d and the treatment course ranged from two weeks to six weeks. There was significant difference between the Danhong injection treatment group and the control group in reducing UAER [MD=-27.08, 95%CI (-30.40, -24.02)]. Although the authors concluded “Danhong can improve UAER of DN”, they had to admit that “conclusive results cannot be made about the effectiveness and safety of Danhong for DN” (p. 1087) because all of the included studies were classified as grade C in methodology (the possibility of high risk of bias).

Tongxinluo

A systematic review (2010) assessed the clinical efficacy and safety of Tongxinluo capsule in the treatment of DN [92]. 11 Chinese RCTs were included and all of them used ITT analysis. The authors classified the 11 RCTs as B grade in methodology (having moderate bias). Compared with no treatment, Tongxinluo capsule could significantly reduce UAER [WMD=-38.88, 95%CI (-60.24, -17.52)]. Interestingly, Tongxinluo capsule was similar to no treatment in improving serum creatinine.

Other TCM

Zhang et al. (2009) conducted a meta-analysis to evaluate the anti-proteinuric effects of TCM clearing heat and activating blood in DN [93]. Eight RCTs were included and the primary outcome measure was the UAE level. The results of meta-analysis demonstrated that the efficacy of TCM clearing heat and activating blood might be similar to ACEI or ARB in reducing 24h proteinuria level (WMD=-1.81, 95%CI: -3.59 to -0.04). Compared with western medicine alone, combination therapy was superior in reducing 24h proteinuria and UAE. Due to the poor methodology of all eight observational RCTs, results of the meta-analysis were not valid. A systematic review (2012) was published to assess the combination therapy with TCM and losartan in the treatment of DN [94]. 28 studies were included and all were classified as C grade (probability of high risk of bias). The results of meta-analysis demonstrated that the combination therapy was superior to losartan alone in reducing UAER [WMD=-47.05, 95%CI (-64.99,-29.11)] and 24-h proteinuria [WMD=-0.56, 95%CI (-0.75,-0.37)]. However, it is almost impossible to arrive at firm conclusions because the observational studies were not sound.

A systematic review and meta-analysis (2013) published in Evidence-based Complementary and Alternative Medicine (eCAM) evaluated the effect of Chinese herbal medicine (CHM) on albuminuria in DN patients [73]. It included 29 trials involving 2440 participants and the results were positive for CHM. Compared with placebo, CHM was more effective in reducing UAER (mean difference [MD] -82.95 μ g/min, [-138.64, -27.26]) and proteinuria (MD -565.99 mg/24 h, [-892.41, -239.57]). CHM was even superior to ACEI or ARB in reducing UAER (MD -13.41 μ g/min, [-20.63, -6.19]) and proteinuria (MD -87.48 mg/24 h, [-142.90, -32.06]). Compared with ACEI/ARB alone, combination therapy with CHM and ACEI/ARB significantly improved UAER (MD -28.18 μ g/min, [-44.4, -11.97]) and proteinuria (MD -26.60 mg/24 h, [-26.73, -26.47]). 11 observational trials were “of superior quality” and “no serious adverse events were reported”. The authors concluded “CHM seems to be an effective and safe therapy option to treat proteinuric patients with DN”, but they also suggested future well designed, large sample size RCT is warranted.

What Are the Limitations with Respect to this Clinical Evidence?

As mentioned above, few RCTs describe the details of randomization, used allocation concealment, blindness or ITT analysis. Most Chinese RCTs reported positive results, but the funnel plots in meta-analyses were usually asymmetric suggesting there was publication bias. “Negative reports are still rarely reported in Chinese journals and this phenomenon should be corrected in the future. [82]” Tu Xiang et al. have elaborated exclusively on the shortcomings of current literature in this area and hence, readers are hereby referred to their recent article on *Curr Vasc Pharmacol* [82]. Although most systematic reviews and meta-analyses arrived at conclusions which favor TCM, their conclusions should be interpreted cautiously because the included studies were usually of sub-optimal methodology. In a word, the limitation of current evidence is methodological shortcoming. It is obvious we cannot draw any firm conclusions if the evidence is not sound.

THE EFFECTS OF TCM ON DN AT THE GENETIC LEVEL

What Are the Effects of TCM on DN at the Genetic Level in Animal Experiments?

Current reports studying the genetic effects of TCM indicate that TCM might exert benefits on DN by regulating some genes in animal experiments.

TCM Extract

Gypenosides

Tao LH et al. (2007) compared the difference of gene expression profile between the DN rats and the gypenosides treated DN rats [95]. This animal experiment reported gypenosides could improve blood glucose, proteinuria and SCr, compared with DN rats. The major finding

was the alteration of the gene’s expression: 135 genes altered between the DN model rats and the gypenosides treated DN rats; 31 genes up-regulated; and 104 genes down-regulated. Some altered genes are listed in Table 2. Now that NM-053336 and NM-147205 genes are related to advanced glycosylation end products (AGEs), the authors concluded gypenosides conferred renal benefits by inhibiting the formation of AGEs.

Table 2. Altered genes between the DN model rats and the gypenosides treated DN rats in the article published by Tao LH et al

Breviscapine

Only one article (2008) explored the genetic effect of breviscapine in DN animal models [96]. In the kidney tissues of diabetic rats induced by streptozotocin (STZ), the mRNA expression level of the p47phox gene significantly increased, which indicated the oxidative stress was enhanced. The diabetic rats given breviscapine showed not only improved serum creatinine (SCr) and blood urea nitrogen (BUN), but also reduced mRNA expression levels of the p47phox gene. The authors concluded that their experiment indicated that breviscapine could ameliorate renal function of diabetic rats by inhibiting the oxidative stress in the kidney.

Artemisinin

Zhou FJ et al. (2014) studied the effects of artemisinin on the genetic expression of c-jun and c-fos in diabetic rats induced by STZ injection [97]. The histomorphology in the artemisinin treated group were significantly improved, compared with the diabetic rats. Using immunohistochemistry and reverse transcription-polymerase chain reaction (RT-PCR) methods, the authors detected the changes of c-jun gene and c-fos gene in the kidney tissues: their mRNA and protein expression significantly increased in diabetic rats and the elevation was significantly inhibited in artemisinin treated rats. The conclusion was as follows: artemisinin could ameliorate renal function injury and pathological changes in diabetic rats by inhibiting the expression of c-jun gene and c-fos gene in kidney tissues.

Individual Traditional Chinese Medicinal Herb

Astragalus

Astragalus not only reduced the levels of proteinuria, SCr and BUN in humans, but also in animals. Applying gene chip technology produced encouraging results. An analysis of 88 genes altered between DN mice induced by STZ and DN mice treated by astragalus resulted in 81 genes being changed in the opposite direction and the remaining 7 genes being changed in the

same direction [98]. The altered genes were associated with metabolism, inflammation and immunity, signal transduction, etc. Some altered genes are listed in Table 3.

Table 3. Altered genes between the DN model mice and the astragalus treated DN mice in the article published by Hong XP et al.

Formulae

Shenxiao Kang (SXX)

During 2006 – 2012, Jiang DY and his team published a six-part series of articles to study the expression difference of various genes in DN rats induced by STZ and in the rats given SXX [99-104]. An array of technology was applied in their publication, such as electron microscopy, gene chip technology, RT-PCR, etc. In conclusion, all of their publications reported that SXX could improve the levels of proteinuria, SCr, BUN and the histopathological changes of DN rats. The authors reported that Gna12, Eif3s8, myosin Va were down-regulated and that S100A9, Cxcl12 and CcL5mRNA were up-regulated in the kidney tissues. SXX could up-regulate Gna12 [99], Eif3s8 [100] and myosin Va [101] and down-regulate S100A9 [102], Cxcl12 [103] and CcL5mRNA [104]. The authors concluded that SXX exerted benefits in DN rats by regulating these genes.

What Are the Effects of TCM on DN at the Genetic Level in Humans?

Articles studying the genetic effects of TCM on DN patients were scarce. Two identified articles explored the genetic effects of TCM formulae.

Xu Xun et al. (2011) carried out a clinical study to assess the effects of Tangshen Formula (TSF) on three hemodynamic susceptibility genes [105]. 31 DN patients given TSF for six months and 23 healthy subjects were the controls. Glomerular filtration rate (GFR), AGT gene, AGTR₂ gene, ADR β ₃ gene were measured at month 3 and month 6. The results showed that the GFR significantly improved at month 3 and then, continued to improve at month 6. The expression of the three genes gradually increased within six months and approached to normal levels. The amelioration of the three genes at month 6 was better than that at month 3. The authors postulated that TSF could inhibit angiotensin-converting enzyme (ACE) in the rennin-angiotensin system (RAS) and play a role like an ACE inhibitor, by regulating the AGT gene and AGTR₂ gene. Their second hypothesis was that TSF improved GFR by improving insulin resistance via ADR β ₃. The expression trend chart of the three genes were highly consistent, which suggested “the mechanism of the clinical efficacy of TSF has multi-pathways”. Wang HW and his team (2013) published an article to study the genetic effects of TCM supplementing *Qi* and nourishing *Yin* on patients with DN [106]. 65 S were included; for three months they took Tangwei Kang capsule, which is a patented TCM - supplementing *Qi* and nourishing *Yin*. The serum homocysteine (Hcy) and methylene-tetrahydrofolate reductase (MTHFR) gene polymorphism were measured by enzyme-linked immuno sorbent assay (ELISA) and the polymerase chain reaction - restriction enzyme fragment length polymorphism (PCR-RFLP) technique, respectively. The values of the 65 S were measured at the beginning and the end of the study. The results showed that TCM could significantly decrease the Hcy levels in DN patients. 44 S had MTHFR C677T gene mutation and the MTHFR gene polymorphism did not change in patients receiving TCM. The authors explained the results as follows: Tangwei Kang capsule cannot reverse gene mutation, but could obviously decrease the serum Hcy level and this might be because Tangwei Kang improved the activity decline of the MTHFR caused by the MTHFR C677T gene mutation.

THE ASSOCIATION BETWEEN THE CLINICAL EVIDENCE AND THE GENETIC EFFECTS OF TCM

What Is the Association?

Articles exploring the association between the clinical efficacy and the genetic effects of TCM were scarce (Reviewed 1979-2014). Only one published article addressed this issue [107]. 60 DN patients were randomly allocated to the Xiao SiWu Tang (XSWT) group and the captopril group. Proteinuria decreased in both groups and there was no significant difference between the two groups. The XSWT could significantly improve hemodynamic parameters, but the captopril failed. The ACE gene polymorphism was also tested. As a result, the authors detected that various genotypes have obvious differences in efficacy; DD genotype and D allele were associated with clinical efficacy of XSWT.

The clinical efficacy is the fundamental basis for complementary and alternative medicine. Therefore, the clinical evidence of TCM in the treatment of DN is the key to many questions. Current literature discloses that there is impoverished evidence, but new persuasive evidence is emerging. At least, for proteinuria, TCM may be promising. On the other hand, it is notable that current literature reveals that the genetic effects of TCM were primarily established on DN

animal models. For example, SXK may be effective in altering the expression of some rat genes, but there is not any sound evidence to support its application in proteinuric DN human patients. Those TCM which have sound clinical anti-proteinuric evidence have not been studied at the genetic level, such as QYXK capsule. However, the anti- proteinuric effect of TCM may be conferred by regulating gene expression – breviscapine and astragalus are good examples. In short, the association between the clinical evidence and the genetic effects of TCM is currently lacking.

How to Relate Them?

Although it is not easy to relate clinical evidence and the genetic effects of TCM, if the TCM community intends to push on with TCM-gene research, the relationship has to be taken seriously. It is obvious that TCM needs the translational conception to bridge the gap between achievements from the research lab and hands-on clinical practice. From a holistic perspective, the balance of the *Tao* in medicine is clinical TCM evidence, observation and documentation of genetic effect, comparison/inclusion of western medicine, and creating a new east/west synthesis model. Current clinical evidence may indicate which TCM deserves investigation. Genes disclosed by animal experiments may be good targets to study. When a well-designed large sample size RCT is carried out, it may be the best chance for TCM to explore the solid genetic effects. When sound clinical evidence concerning the genetic evidence is established, it will be invaluable to guide TCM clinical practice and research.

SUMMARIZATION OF CURRENT LITERATURE

Clinical Evidence

1. A large number of RCTs produced positive results with respect to TCM for proteinuria in patients with DN.
2. RCTs of high methodological quality in this area remain scarce.
3. Systematic reviews or meta-analyses cannot arrive at firm conclusions because the included studies are usually of sub-optimal methodology.

Genetic Effects

1. Current literature reports that TCM may affect some particular genes on DN etiology.
2. TCM may alter the expression of the genetic profile in patients with DN.
3. TCM which has been reported to possess genetic effects are not supported by strong clinical evidence.

CONCLUSION

The current literature demonstrates a disconnect between clinical evidence and demonstrable TCM genetic effects; stronger correlations are needed.

Conflict of Interest

None declared.

ACKNOWLEDGMENTS

The present study is funded by the Sichuan Province 2014: Support Project in Science & Technology (CKY2014007) and supported by Demonstration Project Chengdu City - 2014: Improvement of Livelihood through Science & Technology (2014-HM02-00014-SF).

ABSTRACT

Ansamycins are composed of secondary metabolites possessing a high degree of activity against numerous types of Gram-positive and Gram-negative bacteria. Structurally, ansamycins are characterized by the presence of core structures including an aromatic moiety (benzene or naphthalene derivative) and an aliphatic chain. Most ansamycins were isolated and characterized from Actinomycetes, while a few were mined in higher plants, for example, maytansine and colubrinol. Due to the development of microbiological techniques, genetic engineering and recombinant proteins, a wealth of different types of ansamycins have been mined along with their biosynthetic gene clusters. This resulted in developed strategies for enhancement of ansamycin production as well as synthesis of novel structure derivatives. In this chapter, we will describe the biochemistry and genetics of the most important members of ansamycin antibiotics and their applications as cytotoxic, anti-tumor, anti-parasitic and anti-bacterial agents. Thereafter, the future of ansamycins will be discussed to outline the most critically applied aspects in the last.

Keywords: biochemistry, ansamycin, genetics, antibiotics, *Streptomyces*

INTRODUCTION

Since the 1950s, ansamycins, a prominent class of macrocyclic lactam antibiotics produced by various Actinomycetes have been investigated because of their wide range of biological activities. They are named ansamycins, from the Latin *ansa* (which stands for grip), because of their unique structure comprising of an aromatic moiety bridged by an aliphatic chain. Ansamycins contain an aromatic moiety (naphthalene or a benzene derivative) bridged by a polyketide chain (an aliphatic *ansa* chain) terminating in an amide linkage. The aromatic moiety involved in the biosynthesis of ansamycin antibiotics is derived from a 3-amino-5-hydroxybenzoic acid (AHBA) as a precursor of the mC₇N units, which are synthesized via a novel variant of the shikimate pathway. The branching was found to be modified by introduction of glutamine derived nitrogen at an early stage to give 3,4-dideoxy-4-amino-D-*arabino*-heptulosonic acid 7-phosphate (amino-DAHP) instead of the normal shikimate pathway intermediate, 3-deoxy-D-*arabino*-heptulosonic acid 7-phosphate (DAHP), followed by the formation of 5-amino-5-deoxy-3-dehydroshikimic acid (amino-DHS). Finally, DHS is aromatized by the enzyme AHBA synthase to AHBA (Figure 1 and 2).

AHBA appeared to be further activated by a nonribosomal peptide synthetase-like mechanism and enhanced via addition of methylmalonyl and malonyl extender units by a multimodular type 1 PKSs. On the basis of the folding and cyclization features of ansamycin polyketide, AHBA incorporation occurs in two different ways: either by a benzyl ring or a naphthyl ring with an aliphatic *ansa* chain. This reveals the formation of two main subclasses: the benzenoid ansamycins and the naphthalenoid ansamycins. Benzenoid and naphthalenoid ansamycins are further divided according to the differences in the length of their *ansa* chains. Thus, benzenoid ansamycins are divided into 2 groups, i.e., benzenoid ansamycins with C₁₅ *ansa* chains and benzenoid ansamycins with C₁₇ *ansa* chains. The naphthalenoid ansamycins are divided into 3 groups, i.e., naphthalenoid ansamycins with C₁₇ *ansa* chains, naphthalenoid ansamycins with C₂₃ *ansa* chains, and naphthalenoid ansamycins with C₉ *ansa* chains. Recently, new ansamycins were also reported from different species [1, 2, 3, 4].

MAYTANSINOIDS

Maytansinoids are potent cytotoxic agents generally isolated from living organisms such as the higher plant families *Celastraceae*, *Rhamnaceae*, and *Euphorbiaceae*, as well as some mosses. They are 19-membered polyketide macrocyclic lactams belonging to the ansamycin family (Figure 3) [5, 6, 7]. Their molecular architecture is characterized by an aromatic chromophore with an aliphatic chain (ansa chain) connected back to a nonadjacent position through an amide linkage. Despite carrying either benzenic (ansamitocins, geldanamycin, etc) or naphthalenic (rifamycin, naphthomycin) chromophores, genetic and feeding experiments have revealed that all the ansamycins share the same polyketide starter unit, 3-amino-5-hydroxybenzoic acid (AHBA) [8]. Maytansinoids are under clinical trials with significant improvements achieved mainly by conjugation with tumor specific antibodies namely, trastuzumab emtansine (under Phase III), SAR3419 and BT062 (under Phase II), and several others such as BAY 94–9343, BIIB015, IMG529, lorvotuzumab mertansine, SAR566658, IMG529 [9]. The maytansinoid family comprises of several structural analogues such as maytansinol, maytansine, maytansinol 3-propionate, ansamitocin P3, and ansamitocin P4. They exhibit better cytotoxicity than several other known anticancer agents and had shown promising activity in B-16 melanocarcinoma murine solid tumors in addition to anti leukemic activity

against P388 murine lymphocytic leukemia [10, 11, 12]. Recent studies have shown that antibody-maytansinoid-conjugates block the cells at mitosis by suppressing microtubule dynamics similar to the results obtained involving the unconjugated maytansine [13, 14]. An actinomycete, *Actinosynnema pretiosum*, similarly displays the capacity to secrete large amounts of various maytansinoids known as ansamitocins [15].

Figure 3. Structures of maytansinoids.

BENZENOID ANSAMYCINS

Benzenoid ansamycin antibiotics were first isolated in the late 1970s from the culture broths of several *actinomycetes* species and identified as inhibitors of eukaryotic Hsp90, an important cancer target. Considerable interest was generated by their unusual ansa bridge structure, and a number of compounds including ansamitocin, geldanamycin, herbimycin, macbecin, mycotrienin, cytotrienin, and trienomycin were identified.

ANSAMITOCIN

Ansamitocins, an ansamycin family of polyketide macrolactams with potent antitumor activities, were isolated from *Nocardia* sp. No. C-15003. Structurally, they were found to be similar to maytansine and related maytansinoids. Both the structures and antitumor activity of the ansamitocins are similar to those of the maytansinoids from plant sources [16]. Due to their high cytotoxicity, ansamitocins and homologous compounds have been used to conjugate with targeted molecules, such as monoclonal antibodies and folic acid for tumor-targeting therapy [17].

Ansamitocin P-3 is a secondary metabolite of *Actinosynnema pretiosum* ssp. Ansamitocins are a series of complex aromatic compounds including AP-0, AP-2, AP-3, AP-3', and AP-4, among which ansamitocin P-3 is found to be the most active ingredient [18, 19]. In recent years, Ansamitocin P-3 has received lot of attention because of its industrial importance. In the biosynthesis of ansamitocin P-3, 3-amino-5-hydroxybenzoic acid (AHBA) is used as a starter unit [20], and the incorporation of seven PKS extender units yields a 19-membered macrolactam, proansamitocin, which further undergoes a series of post-PKS modifications, including O- and N-methylation, chlorination, epoxidation, O-carbamoylation, and O-acylation for conversion into the bioactive compound, ansamitocin P-3 (Figure 4). Ansamitocin P-3 is

also known to depolymerize microtubules and bind to tubulin in a competitive manner with vinblastine and rhizoxin suggesting that it partially overlaps the vinblastine binding site [21]. Moreover, treatment of MCF-7 cells with ansamitocin P3 resulted in severe disruption of interphase and mitotic microtubules. The affected cells were found to be blocked from mitosis and accumulated p53 and its downstream partner p21 in the nucleus, which subsequently activated apoptotic cell death in the cells [22]. Recently, ansamitocin P-3 was identified as the most potent inducer of murine dendritic cell maturation, which resulted in augmentation of antitumor immunity in tumor-bearing hosts through the activation of *T* cells [23].

Beilstein J. Org. Chem. 2014, 10, 535-543.

GELDANAMYCIN

Geldanamycin, a potent anticancer antibiotic, is a benzoquinone ansamacrolide related to herbimycin, reblastatin, and macbecin. It was first isolated in 1970 from *Streptomyces hygroscopicus* var. *geldanus* var. *nova*. Further, different geldanamycin analogs such as 4,5-dihydrothiazinogeldanamycin, reblastatin, 17-demethoxy-reblastatin, tetracyclic thiazinogeldanamycin and 19-hydroxy-4,5-dihydrogeldanamycin, were reported from the same strain (Figure 5) [24, 25]. Geldanamycin was found to be active against L-1210 and KB cells growing in culture and against the parasite *Syphacia ohlevata*, also shown to display antiviral activity [24, 26]. On the basis of its physical and chemical properties, geldanamycin is a complex molecule consisting of an unsaturated moiety attached to a quinone. The biosynthesis of geldanamycin involves the assembly of 3-amino-5-hydroxybenzoic acid as a starter unit, followed by the addition of extender units such as acetate, propionate, and glycolate to form a polyketide backbone, and further followed by the formation of geldanamycin via post-PKS modification, which includes C-17 hydroxylation, C-17 O-methylation, C-21 oxidation, C-7 carbamoylation, and C-4,5 oxidation. Geldanamycin binds to the N-terminal ATP binding pocket of heat shock protein 90 (Hsp90), which prevents stress-induced cellular damage, stabilizes various oncogenic kinases and influences gene expression e.g., by up-regulating NF-KB. As Hsp90 expression is particularly high in cancer cells and is associated with tumor cell progression, invasion and formation of metastases, as well as development of drug resistance, geldanamycin and its analogues have been considered for treatment of cancer in human cells. Their binding to Hsp90 disrupts the interaction of these proteins with the Hsp90 chaperone complex, preventing normal folding and leading to ubiquitylation and subsequent degradation. Second, geldanamycin treatment induces up-regulation of many proteins through the action of the transcription factor heat shock factor-1. These newly synthesized proteins then work to

restore cellular homeostasis after disruption of Hsp90 function [22]. Geldanamycin may also counteract neuronal injury, an effect attributed to destabilization of RIP1 protein. It was found that cisplatin (CDDP) blocks geldanamycin induced HSF-1-mediated transcription, resulting in decreased stress-responsive protein levels after treatment. The decreased transcription observed when geldanamycin is combined with CDDP is due to CDDP-mediated abrogation of HSF-1 chromatin binding, thereby preventing up-regulation of stress-responsive transcripts for genes such as Hsp70 and Hsp27 [27].

Figure 5. Structures of geldanamycin and its analogs from *Streptomyces hygroscopicus*.

So far, lots of geldanamycin derivatives have been reported and some of the less hepatotoxic derivatives entered into clinical trials, for instance, 17-allylamino-17-demethoxygeldanamycin (tanespimycin, 17-AAG) and 17-[2-(dimethylamino)ethyl]amino-17-demethoxygeldanamycin (alvespimycin, 17-DMAG) [28]. However, development of new generations of GA derivatives by structure modification has not yet been accomplished. 17-AAG showed some promise in phase II trials for the treatment of breast cancer. However, the clinical trial was terminated, indicating that geldanamycin derivatives with less hepatotoxicity are required. Recently, incorporation of phenylethylamine scaffold into the C-17 position of geldanamycin through application of structure-based bioisosterism was attempted to not only increase the binding of 17-phenylethylaminegeldanamycins to Hsp90, but also to decrease the hepatotoxicity [29]. SNX-25a, with a 2-(trans-4-hydroxy-cyclohexylamino) side chain, is a novel 2-aminobenzamide inhibitor of Hsp90 optimized through structure-activity relationship (SAR) explorations for high Hsp90 affinity and was tested against several human cancer cells

then compared with 17-AAG. Initially, the growth inhibitory effects of SNX-25a and 17-AAG on human cancer lines were investigated and demonstrated that SNX-25a displayed better activity than 17-AAG in human cancer cells. This may be mediated by G2 phase arrest and cell apoptosis; and provoked by the down-regulation of Hsp90 client proteins. In addition, SNX-25a, an Hsp90 inhibitor, displayed higher affinity for Hsp90 than the typical Hsp90 inhibitor 17-AAG in molecular docking. [30].

MACBECIN

In 1979, while screening for new antibiotics, the benzenoid ansamycins macbecins I and II (Figure 6) were detected after fermentation of the actinomycete strain No. C-14919 (N-2001). Macbecins I and II were antifungal and antiprotozoal, whereas macbecins I and II do not show any specific activity against eukaryotic microorganisms. Hence the biological activities of macbecins I and II are distinguishable from ansamitocins and other related compounds such as maytansine [31]. Macbecin II, a heat shock protein (Hsp90) inhibitor, is a DNA antimetabolite that induces breaks in double-stranded DNA, possibly by means of p53-mediated apoptosis. Although Macbecin II functions as a Hsp90 inhibitor, it is unclear whether this is its mechanism of action for increased activity in SMAD4-negative cells, as geldanamycin does not display similar activity. On the other hand, reduction in TSC2 (siRNAs) has been shown to activate mammalian target of rapamycin mediated cellular hyperplasia and hypertrophy. Cells with reduced levels of TSC2 are less susceptible to macbecin II. In some systems, loss of mammalian target of rapamycin activity is associated with p53-dependent apoptosis. Hence, enhancement of cellular growth through loss of TSC2 may help overcome the apoptotic effects of DNA damage. Furthermore, TSC2 knockdown affected the activity of macbecin II but not cisplatin, further implicating distinct p53-related cellular responses [32].

Figure 6. Structures of macbecin I and II.

HERBIMYCIN

In 1978, herbimycin was isolated from the fermentation broth of *Streptomyces hygroscopicus* strain No. AM-3672. In 1980, herbimycin B (Figure 7) was isolated from the

same strain, as was herbimycin C in 1986 (Figure 7). Herbimycin was found to have potent herbicidal activity against most mono- and di-cotyledonous plants, especially against *Cyperus microiria* STEUD. However, *Oryza sativa* showed strong resistance to herbimycin where as Herbimycin B was less effective. Moreover, herbimycin B showed potent anti-tobacco mosaic virus activity. Herbimycin A (Figure 7) may reduce hepatic ischemia-reperfusion injury through the protective effect of hepatocyte against radical injury, but not by preventing radical induced lipid peroxidation and oxidative stress. Herbimycin A did not inhibit lipid peroxidation or oxidative stress in reperfused liver tissue, but reduced liver damage and hepatocyte injury. It also appears to cause the heat shock transcription factor-1 (HSF-1) to bind the heat shock element, leading to transcriptional activation of heat shock protein (HSP) genes and providing protection against insult at nontoxic concentrations. It has been shown to induce transcription of HSP70, HSP90, HSP25, and HSP30 in a number of cell types.

Figure 7. Structures of herbimycin A, B and C.

On the other hand, herbimycin A has been reported to inhibit the induction of apoptosis, which is mediated by intracellular signaling. If radical-induced cell injury is also mediated by intracellular signaling, it may be that herbimycin A, a potent tyrosine kinase inhibitor, inhibits the signaling via tyrosine phosphorylation. Because herbimycin A reduces hepatic reperfusion injury through a different mechanism from antioxidants, synergistic protective effects may be achieved by the addition of herbimycin A into preservation solutions. Herbimycin A also has protective effects on radical-induced injury in human vascular endothelial cells. Furthermore, herbimycin A promotes the degradation of transmembrane tyrosine kinase receptors by the 20S proteasome [33]. Based on the discovery of gonad-specific expression of the cellular Src tyrosine kinase SmTK3, inhibition experiments with the Src-kinase inhibitor herbimycin A led to reduced mitotic activity and egg production in paired *S. mansoni* females. The comparison of both inhibitor treatments pointed to a stronger reduction of both parameters following herbimycin A treatment. The strongest influence on mitotic activity and egg production was observed when both inhibitors were combined. Herbimycin A is an inhibitor of viral Src and c-Src activity, therefore, its effect on Hepatitis C virus replication is indeed mainly due to the

inhibition of c- Src function. This is further supported by the observation that down-regulation of c-Src expression by siRNA is accompanied by a reduction in the inhibitory concentration (IC₅₀) of herbimycin A, which is commensurate to the reduction of c-Src protein levels [34, 35].

Figure 8. Structure of Herbimycin D, E and F.

Recently, three new ansamycin analogues, herbimycins D-F (Figure 8), were isolated from *Streptomyces* sp. RM-7-15. Herbimycin D was isolated as a pale yellow solid material composed of mercaptoacetamide-bearing ansamycins. Herbimycin E was isolated as a purple solid and its NMR chemical shifts were in agreement with those of the fully characterized *ortho*-quinone natural product 7-hydroxy-8-methoxymalbranicin-5,6-quinone. Similarly, herbimycin F was isolated as a white solid. Less than 25 bacterial *ortho*-quinones metabolites have been reported thus far. Within this context, the herbimycin E reported herein represents the first example of an *ortho*-quinone ansamycin. Similarly, unusual intramolecular etheric linkage was observed in herbimycin F. Unlike herbimycin A, which was equipotent in cancer cell line cytotoxicity assays, the new analogues (herbimycins D-F) did not exhibit any cytotoxicity or antibacterial and antifungal activities with similar affinity. Rather, these compounds were found to bind the Hsp90 α N-terminal domain with similar affinity to that of herbimycin A [36].

MYCOTRIENINS (ANSATRIENINS), TRIERIXIN AND QUINOTRIERIXIN

Mycotrienins, a unique class of benzoquinone ansamycins antibiotics, are structurally related to herbimycin A in that they also contain a quinone/hydroquinone system and are produced by *Streptomyces rishiriensis* T-23. The reduced form was identified, via comparison with the previously reported mycotrienin, as an antifungal antibiotic. A different form was characterized as its oxido- form, hence, the name mycotrienin I was given to the latter and mycotrienin II to the former. Ansatrienins A and B were also isolated from *Streptomyces collinus* and *Streptomyces rishiriensis* with different alanine stereochemistry in comparison to mycotrienin I and II (Figure 9). The isolation of two minor components, ansatrienins A2 and A3 were also reported, wherein the cyclohexyl group of ansatrienin A is replaced by a 2-methylbutyryl group and an isovaleryl group, respectively. Further screening for minor components of mycotrienins resulted in the isolation of two metabolites named 22-O-methylmycotrienin II and 19-deoxymycotrienin II. Mycotrienin I and mycotrienin II are active against fungi and yeasts, but inactive against bacteria [37, 38]. Mycotrienins are a possible target for pp60^{c-src} kinase in fetal rat long bones. The structural relations of different mycotrienin analogues that inhibit bone resorption closely reflect the ability of these compounds to inhibit pp60^{c-src}. Hence, pp60^{c-src} is essential for normal osteoclastic bone resorption and point to a potential for pharmacologic intervention in the bone resorption process at the level of pp60^{c-src}. Therefore, the mycotrienins may have some therapeutic potential as bone resorption inhibitors in diseases where bone resorption is increased [39]. Similarly, mycotrienin II, inhibited the cell-surface intercellular adhesion molecule-1 expression induced by TNF- α more strongly than that induced by IL-1 α in human lung carcinoma A549 cells. Mycotrienin II was found to inhibit protein synthesis in intact living cells, as well as in cell-free translation systems. Several compounds of the triene-ansamycin group (that is, mycotrienin I, trienomycin A, trierixin, quinotrierixin and quinotrierixin HQ) also inhibited intercellular adhesion molecule-1 expression, as well as cell-free translation in a manner similar to mycotrienin II, namely thru direct inhibition of translation. This limits inhibition of intercellular adhesion molecule-1 expression induced by pro-inflammatory cytokines [40].

Trierixin, a new member of the triene ansamycin group has also been isolated from *Streptomyces* sp. AC 654. Trierixin inhibits thapsigargin-induced XBP1-luciferase activation in HeLa/XBP1-luc cells and endogenous XBP1 splicing in HeLa cells. In the process of isolating trierixin, we isolated structurally related mycotrienin II and trienomycin A, both inhibitors of ER stress-induced XBP1 activation, from a culture broth of a trierixin-producing strain. Trierixin possessed a 21-membered macrocyclic lactam (Figure 10), which contains a methylthio-benzenediol structure and a cyclohexanecarbonylalanine moiety, and was thus labeled as 21-thiomethylmycotrienin II [41, 42].

Quinotrierixin, demethyltrienomycin A, demethyltrienomycin B and demethyltrienomycinol were isolated from a culture broth of *Streptomyces* sp. PAE37 and found to be inhibitors of ER stress-induced X-box binding protein 1 activation. All four possessed 21-membered macrocyclic lactams including triene moieties. Quinotrierixin inhibited thapsigargin-induced X-box binding protein 1 activation in HeLa cells, whereas demethyltrienomycin A and mycotrienin I inhibited ER stress-induced X-box binding protein 1 activation. A SAR study showed that the OH group at C-13 was crucial and that the CH₃ group at C-14 was important for the X-box binding protein 1 inhibitory activity [43, 44].

Figure 9. Structure of Mycotrienin I and II.

Figure 10. Structure of trierixin.

CYTOTRIENIN

Cytotrienin A (Figure 1A), 21-membered cyclic lactam of the triene-ansamycin family (Figure 11), was initially identified as an inducer of apoptosis in human leukemia HL-60 cells. Isolated from *Streptomyces* sp. RK95-74, cytotrienin A contains a trieneansamycin, 1-aminocyclopropane carboxylic acid and 1-cyclohexene-1-carboxylic acid moieties [45]. Cytotrienin A, as an apoptosis inducer, marks morphological changes of the cell including membrane blebbing, cell shrinkage, chromatin condensation, DNA cleavage, and fragmentation of the cell into apoptotic bodies. It also activates signaling pathways of JNK/SAPK and p38 MAPK. The p36 MBP kinase activated by cytotrienin A phosphorylates MBP to a greater extent than c-Jun and ATF-2. It was also reported that MST1/Krs2 is cleaved by caspase-3-like activity during Fas-induced apoptosis. It is possible that most apoptotic signals including the Fas-mediated signal and the cytotrienin-induced signal activate several pathways for apoptosis in target cells. The caspase-mediated proteolytic activation of MST/Krs proteins in cytotrienin A-sensitive and -resistant human tumor cell lines were further investigated. Cytotrienin A was also found to inhibit eukaryotic protein synthesis by targeting translation elongation and interfering with eukaryotic elongation factor 1A function. The molecule prevents HUVEC tube formation and reduces micro vessel formation in chorioallantoic membrane assays. Furthermore, it was found to inhibit the cell surface expression of intercellular adhesion molecule-1 (ICAM-1) induced by tumor necrosis factor (TNF)- α more strongly than the expression induced by interleukin (IL)-1 α . Hence, cytotrienin A is a translation inhibitor that induces the TACE-mediated ectodomain shedding of TNF receptor 1 via the activation of ERK and p38 MAP kinase [46].

Figure 11. Structure of cytotrienin A.

TRIENOMYCIN

An antibiotic with triene-containing C17-benzene ansamycins known as trienomycins A (Figure 12) was isolated from the culture broth of *Streptomyces* sp. No. 83-16 in 1985 and from *Streptomyces* sp. G91614 in 2002. Isolation of trienomycins A was followed by the isolation

of a series of trienomycins which include trienomycins B-G. The trienomycin group is closely related to mycotrienins and ansatrienins in structure. However, trienomycins are unique among the benzenoid ansamycin antibiotics in that trienomycins A - E do not contain a p-quinone or p-hydroquinone moiety. The benzenoid moiety of the trienomycin group is rather similar to those of maytansinoids (higher plant origin) and ansamitocins (microbial origin). Similar to mycotrienins I and II and ansatrienins A and B, the hexahydrobenzoyl moiety was found in the structure of trienomycin A, whereas the 3-methylbutyryl (isovaleryl) and 2-methylbutyryl moieties were found in trienomycins B and C respectively. Instead of the hexahydrobenzoyl moiety of trienomycin A, a tetrahydrobenzoyl moiety is attached to the alanyl moiety in trienomycin D. In contrast, trienomycin E is quite similar to trienomycin B except for the acyl group attached to the alanyl group, which indicates that the 4-methylpentyl moiety is attached to the alanyl moiety of trienomycin E [47, 48].

Figure 12. Structure of Trienomycin A.

In the year 2002, trienomycin G (Figure 13) along with trienomycin A, were reported to be isolated from *Streptomyces* sp. G91614. As in trienomycin A, the N-hexahydrobenzoyl alanine moiety of trienomycin G was found to be linked to C-13 instead of C-11. Thus, trienomycin G is a structural isomer of trienomycin A, only differing in the linkage position of the N-hexahydrobenzoyl alanine side chain to the ansa moiety. Trienomycins A-E exhibited considerable cytotoxic activity against HeLa S3 cells without showing activity against the microorganisms tested including bacteria, fungi and yeast. Trienomycins D and E exhibited 2 ~ 5-fold weaker activities against HeLa S3 cells than trienomycin A. On the other hand, trienomycin G and trienomycin A displayed potent inhibitory activity against Nitric oxide production in BV-2 microglia cells stimulated with LPS. Trienomycin G inhibited Nitric oxide production more strongly than that of trienomycin A. This result indicates that the position of the N-hexahydrobenzoyl alanine moiety affects the activity [49].

Figure 13. Structure of Trienomycin G.

NAPHTHALENOID ANSAMYCINS

Naphthalenoid ansamycins are best known for their antimicrobial activities, which are mediated by a specific inhibition of bacterial RNA polymerase. They are used for the treatment of leprosy, tuberculosis, and AIDS-related mycobacterial infections. Naphthalenoid ansamycins include salinisporamycin, hygrocins, rifamycin drugs as well as the rifamycin derivatives rifampicin (or rifampin), rifabutin, and rifapentine.

RIFAMYCIN

Rifamycin, a naphthalenic ansamycin antibiotic was isolated from two strains of *A. mediterranei*, S699 and LBGA 3136, and the major products of the complex were named rifamycin A, B, C, D and E (Figure 14). The rifamycin polyketide synthase (*rif* PKS) gene clusters were essentially identical in both of these strains. The partially characterized (~4 kb) *rif* PKS-like gene cluster from *A. rifamycinica* DSM 46095 showed 10% differences in nucleotide sequences compared to the *rif* PKS clusters from S699 and LBGA 3136.

The *rif* PKS gene cluster in strain 46095 was represented by a continuous fragment of ~85 kb that contained *rifA*, *rifB*, *rifC*, *rifD*, and *rifE* open reading frames (ORFs). The acyltransferase (AT) and ketosynthase (KS) domains present on these ORFs showed 90% homology to those on *A. mediterranei* S699 (4). Apart from a unique *rif* PKS cluster, eight other PKS, seven NRPS, and three hybrid NRPS/PKS clusters were present in the genome. The sequence information of a novel rifamycin biosynthetic gene cluster of *A. rifamycinica* 46095 will be helpful in the analysis of the structure of the polyketide produced by this strain [50]. Rifamycin B related compounds, such as rifamycin O and rifamycin S, were obtained by the chemical transformation of rifamycin B. Rifamycin L, rifamycin SV and rifamycin Y were isolated from the cultured broth of *Streptomyces mediterranei*. Rifamycin derivatives have also shown excellent activity against opportunistic pathogens in the AIDS complex of diseases, as well as against HIV and related oncogenic viruses due to the inhibition of the viral reverse transcriptase.

Figure 14. Pathway of Rifamycin B biosynthesis.

RIFAMPICIN

Since 1960, Rifampicin, a synthetically modified form of rifamycin (Figure 15), was used as the first-line therapy drug in the treatment of tuberculosis and other mycobacterial infections with low toxicity. Rifampicin prevents the assembly of DNA-dependent RNA polymerases, thereby inhibiting protein synthesis and cell growth in bacteria while preventing the assembly of DNA and protein into mature virus particles. The block, which occurs at the stage of the viral envelope formation, can be rapidly reversed by removal of the drug. It also inhibits the growth of poxviruses and adenovirus and can prevent the maturation of infectious viruses until quite late in the growth cycle. Rifampicin reaches maximal serum concentration in 1–4 h after application and its plasma half-time is 2–5 h. The lipophilic ansa chain is mainly responsible for the transport of the drug across the blood-brain barrier into the brain parenchyma [1, 51]. However, the emergence and spread of multidrug-resistant tuberculosis (MDR-TB) and extensively drug-resistant tuberculosis (XDR-TB) pose a major public health problem threat worldwide. According to the World Health Organization, 450,000 new cases of MDR-TB were documented worldwide in 2012. Thus, a sensitive and specific diagnostic tool is required to initiate the appropriate therapy and reduce the spread of multidrug-resistant *M. tuberculosis*.

strains. The emergence of resistance during therapy with rifamycin can generally be avoided with the use of adequate combination therapy. The clinically significant resistance mechanism is mutation in the 81-bp region of the *rpoB* gene, which encodes the target of rifamycin, the β subunit of bacterial DNA-dependent RNA polymerase. The portion of this sequence defined as cluster I is particularly important for high-level resistance. As a result of the high degree of conservation of DNA-dependent RNA polymerase, including in this β region, the mutations that determine resistance are also conserved across species. Mutations are most often found in three specific codons of the consensus sequence and Ser531Leu substitution in β predominates in mycobacteria and some other species. Cross-resistance appears to be complete among the rifamycins currently used to treat mycobacterial diseases. Mutations can have profound effects on transcription rate, initiation, pausing and termination. As a result of the central role played by DNA-dependent RNA polymerase in the bacterial cell, mutations often affect a number of physiological processes. On the other hand, better analogs of rifamycin can be generated to overcome the emergence of rifamycin resistance such as with rifampicin-resistant *M. tuberculosis* strains, OSDD 321 and OSDD 206, which contain the S531L mutation, and OSDD 55, which has the H526T mutation in the DNA-dependent RNA polymerase β subunit. These mutations appear to alter the affinity of DNA-dependent RNA polymerase to rifampicin. In addition, drug resistant mutations can disrupt hydrogen bonding in the polyketide ansa chain which was confirmed by the fact that 24-desmethylrifampicin showed improved activity against rifampicin resistant *M. tuberculosis*. The loss of the methyl group in this compound is postulated to lead to conformational changes in the ansa chain that allow for more flexibility of the compound to bind mutated DNA-dependent RNA polymerase[52, 53].

Figure 15. Structure of Rifampicin.

Recently, it was demonstrated that rifampicin inhibits the lipopolysaccharide -stimulated expression of Toll- like receptor-4. When cortical neurons were co-cultured with lipopolysaccharide -stimulated BV2 microglia, pre-treatment with rifampicin increased neuronal viability and reduced the number of apoptotic cells. Hence, rifampicin exerts strong brain protective effects in various in vivo and in vitro models of neurodegenerative diseases including Stroke, Parkinson, and Alzheimer. Pilot clinical studies indicate that patients with neurodegenerative diseases may benefit from rifampicin treatment. These promising findings

should be further explored in larger preclinical therapeutic studies and even further in randomized early phase clinical trials. Similarly, rifamycin SV is derived from rifamycin B by removal of the glycolic group bound to C-4 and has clinical uses in the treatment of bacterial infections due to binding and inhibition of bacterial DNA-dependent RNA polymerase, which is also able to bind the BCL6-POZ domain and inhibits BCL6 transcriptional repression. Hence, rifamycin SV can inhibit amyloid fibril formation through disruption of interactions between fibril aromatic rings required for elongation. Rifaximin does not have this effect [54, 55, 56].

RIFABUTIN

Since 1981, rifabutin, a spiro-piperidyl derivative of the parent compound rifamycin S (Figure 16), has been used for the treatment of disseminated *Mycobacterium avium intracellulare* infection in patients with AIDS. It was found to have significant activity in animal models against both *Mycobacterium tuberculosis* and *Mycobacterium leprae* compared to rifampin and studies in 1987 found that rifabutin is active against some rifampin-resistant strains of both species. Its significance for the treatment of *M. tuberculosis* was confirmed in 1996 and at lower doses than rifampicin. The drug has a long half-life (16 hr) in humans and a marked tissue tropism, with tissue levels five- to 10-fold higher than in serum. In animals, rifabutin was no more toxic than rifampin. In some cases, rifabutin may retain its activity against isolates resistant to rifampicin, possibly due to differences in affinity for mycobacterial RNA polymerase or additional inhibition of DNA biosynthesis [57, 58].

Figure 16. Structure of Rifabutin.

Rifabutin displays good in vitro activity against *Helicobacter pylori*, and the prevalence rate of rifabutin resistance is very low at only about 1%. Rifabutin should be limited to patients where previous (multiple) eradication regimens with key antibiotics such as amoxicillin, clarithromycin, metronidazole, tetracycline and levofloxacin have failed. Thus, it is suggested that the position of rifabutin in the algorithm of *Helicobacter pylori* treatment is as a fourth-line rescue regimen; that is, administered only after failure of three eradication regimens [59].

Rifabutin has long post antibiotic effect against *M. tuberculosis* and *M. avium* Complex, shows extensive distribution in various tissues, and readily penetrates cell membranes of leucocytes. These characteristics and their variations among patients can considerably influence the outcome of rifabutin-containing anti-mycobacterial therapy and therefore might be one of the explanations of favorable efficacy despite lower plasma concentrations of rifabutin. Low isoniazid plasma concentration is independently related to treatment failure of HIV/TB co-infection [60].

The American Thoracic Society guidelines classify rifabutin as a first-line anti-TB drug. In addition the WHO guidelines recently added rifabutin to the list of group 1 drugs, the most potent and best-tolerated anti-TB agents. Rifampicin is an essential component of TB treatment and has been referred to as the most important anti-TB agent because of its excellent sterilizing capacity. Considering that rifabutin is more active than rifampicin against slow-growing mycobacteria, including *Mycobacterium tuberculosis*, and that rifabutin has a similar potency to rifampicin in the treatment of drug susceptible TB, the promising outcome in the rifabutin group is most likely related to the outstanding potency of rifabutin against *M. tuberculosis*. Minimum inhibitory concentration distributions for rifabutin were above the epidemiological cut-off, but below the standard critical concentration. The WHO Guidelines for the treatment of HIV-associated tuberculosis recommend that treatment is given daily throughout the intensive and continuation phases of antituberculosis treatment. A daily dose of rifabutin is in line with these recommendations. This would facilitate the important programmatic issue of combining rifabutin with other antituberculosis medications as a fixed-dose combination pill to be taken on a daily basis [61, 62, 63].

RIFAPENTINE

In 1998, rifapentine, a potent antimycobacterial rifamycin (Figure 17) antibiotic was approved by the Food and Drug Administration as an alternative to rifampin in treatment regimens for patients with tuberculosis. Rifapentine is under active investigation as a potent drug that may help shorten the duration of tuberculosis treatment. There have been many reports on the antimicrobial activity of rifapentine in vitro, in macrophages, and in mice. It was found to be 2–4 times as active as rifampicin against *Mycobacterium tuberculosis*. The serum half-life of rifapentine is several times longer and it has greater bactericidal dosing than rifampicin. It has been approved as a first-line drug for once or twice-weekly dosing in the treatment of tuberculosis.

Rifapentine is being evaluated as an agent to shorten the duration of tuberculosis treatment. Applying a nonlinear mixed-effect modeling approach to rich population pharmacokinetic data collected from individuals receiving daily doses of rifapentine ranging from 450 mg to 1,800 mg revealed that the bioavailability of rifapentine decreases with increasing doses beginning at the lowest dose tested. Rifapentine pharmacokinetics is time dependent, but the magnitude of auto induction does not vary with concentration. Clinical trial simulations demonstrate that splitting the dose or taking the dose with food could substantially increase daily rifapentine exposures, which is a significant finding; given that rifapentine activity appears to correlate best with the area under the concentration time ratio and that current dosing achieves concentrations that are still on the steep part of the dose-response curve. With tuberculosis still

globally out of control, it is necessary to undertake studies that allow us to maximize the benefits from the drugs and drug combinations that are available for treatment [64, 65].

Figure 17. Structure of Rifapentine.

SALINISPORAMYCIN

In 2009, salinisporamycin, a new rifamycin antibiotic (Figure 18) was isolated from a culture broth of marine actinomycete identified as *Salinispora arenicola* on the basis of the 16S rRNA sequence. Subsequent biological studies revealed that salinisporamycin not only showed antimicrobial activity, but also inhibited the growth of A549 cells (the human lung adenocarcinoma cell line) [66].

Figure 18. Structure of Salinisporamycin.

HYGROCIN

Streptomyces sp. LZ35 is a 3-amino-5-hydroxy-benzoic acid (AHBA) containing strain with two AHBA synthases. It was isolated from intertidal soil collected in Jimei, Xiamen, P. R. China. This strain can produce two different types of ansamycins: geldanamycin (benzenic ansamycin) and a hygrocins (naphthalenic ansamycin) (Figure 19). Hence, AHBA is common in the biosynthesis of naphthalenic and benzenic ansamycins.

Figure 19. Structure of hygrocins C–E, derivatives of hygrocin A but differ in the configuration at C-2 and the orientation of the C-3,4 double bond. Hygrocins F and G were isomers of hygrocins C and B, respectively, due to the different alkyl oxygen participating in the macrolide ester linkage. (J. Nat. Prod. 2013, 76, 2175–2179).

Hygrocin A and B, along with a derivative of hygrocin A, were previously isolated from *Streptomyces hygroscopicus* ATCC25293. The chemical structures of hygrocins indicated that an AHBA starter unit and eight extender units, including four malonyl-CoA molecules, three methylmalonyl-CoA molecules, and one (2S)-ethylmalonyl-CoA molecule, are employed in the polyketide chain extension. Similarly, hygrocins C–E were shown to have the same planar structure as the “degradation” product. However, since the relative configuration of the

“degradation” product was not elucidated, it cannot be identified as one of the hygroscins C–E. In contrast, hygroscins B–G may be derived from the reactive precursor hygroscin A. The γ lactam of hygroscins C–F is formed in an intramolecular aldol reaction, and formation of the seven-membered lactam ring in hygroscin B and G is possibly due to the attack of the carbonyl-activated methylene on the quinone in a vinylogous fashion. The hygroscins (1–6) were evaluated for cytotoxicity against various human cancer cell lines (breast cancer MDAMB-431 cells, prostate cancer PC3 cells, alveolar basal epithelial cells A549, colorectal cancer SW620 cells, and hepatocellular liver carcinoma cells HepG2). Though the hygroscins tested were structurally quite similar, they showed dramatically different biological activities. Hygroscins C, D, and F were observed to be cytotoxic to human breast cancer MDA-MB-431 cells and prostate cancer PC3 cells, whereas hygroscins B, E, and G showed no toxicity relative to the control. As hygroscins C, D, and E have the same planar structure, the lack of activity of E might be ascribed to the configuration of E with a 3, 4 double bond [67, 68].

NEW BIOACTIVE ANSAMYCIN

Chaxamycins

In 2011 chaxamycins A-D, new bioactive ansamycin type polyketides were isolated from the culture broth of *Streptomyces* sp. strain C34. A unique structural feature of the new ansamycins (A-D) (Figure 20) that distinguishes them from the previously known members of this family is the lack of a methyl group at the olefinic C-16 next to the amide link when compared with previously isolated naphthalenic ansamycins such as the rifamycins, streptovaricins, tolypomycins, the halomicins, naphthomycin, actamycin, and damavaricins, and the bransarols as well as the benzenic ansamycins such as geldanamycin, and the herbimycins and macbecins. Thus, chaxamycin A is the 8-hydroxy-16-demethyl analogue of protostreptovaricin-I while chaxamycin B is the 16-demethyl analogue of protostreptovaricin-I.

Figure 20. Structure of Chaxamycin A-D.

dx.doi.org/10.1021/ol501072x | Org. Lett. 2014, 16, 2752-2755

Figure 21. Proposed Biosynthetic Pathway and Post-PKS Modifications of Juanlimycins A and B.

Chaxamycins A-D possess antibacterial activities against the Gram-positive *S. aureus* ATCC 25923 and the Gram-negative *E. coli* ATCC 25922. Chaxamycin D showed a highly selective antibacterial activity against *S. aureus* ATCC 25923, displaying activity against almost all strains [69, 70].

Juanlimycins

In 2014, juanlimycins A and B, two novel ansamycin macrodilactams with unprecedented feature (Figure 21), were reported in the culture broth of *Streptomyces* sp. LC6. This was determined by analysis of high-resolution ESIMS, 1D and 2D NMR spectroscopic data and X-ray single crystal diffraction study. Juanlimycins A and B were found to be active against *Staphylococcus aureus* ATCC 25923, *Mycobacterium smegmatis* mc2 155 and *Candida albicans* 5314. Juanlimycins A and B are also the first macrodilactams among the reported ansamycins [71].

Chapter 47

BRCA GENE MUTATIONS MEDIATE PARTICULARLY HIGH TNBC RISK BY DEFECTIVE ESTROGEN SIGNALING

ABSTRACT

Ubiquitously expressed protein products of *BRCA1* and *BRCA2* genes are implicated in processes fundamental to all cells, including DNA repair and recombination, checkpoint control of cell cycle, and transcription. *BRCA* gene mutations lead to disruption of *BRCA* proteins in mutation carrier cases and induce susceptibility to specific types of cancer. Among women with germline *BRCA* mutations near 50% of mammary malignancies are triple negative breast cancer (TNBC) presenting with a high grade histologically. Among women with breast cancer, TNBC was established in 57.1% of *BRCA1*-mutation positive and in 23.3% of *BRCA2*-mutation positive cases, whereas in only 13.8% of *BRCA*-proficient women. Although *BRCA* gene mutation carrier women usually exhibit clinical symptoms of defective estrogen receptor (ER) signaling; such as anovulatory infertility and early menopause, the serum estrogen levels of these patients are consequently elevated. In these cases, a compensatory feedback mechanism aims to break through the inherited or acquired ER resistance by increased estrogen synthesis so as to maintain the cellular estrogen surveillance. The higher the estrogen overproduction of *BRCA*-mutation positive cases, the higher the possibility of tumor-free survival. In conclusion, *BRCA1* and *BRCA2* gene mutations seem to increase the breast cancer risk, particularly that of TNBC, in case of insufficient compensation of defective ER signaling. Upregulation of these genes by means of elevated estrogen levels of high parity, artificial hormonal cycle created by oral contraceptives or a pregnancy mimicking high estrogen dose may decrease the excessive cancer risk of *BRCA* mutation positive women.

INTRODUCTION

A small proportion of breast cancer cases, in particular those arising at a young age, are attributable to a highly penetrant, autosomal dominant predisposition to the disease. Twenty years ago, the identification of *BRCA1* gene was announced, the first gene known to strongly predispose to breast cancer when becoming mutated [1]. Identification of *BRCA2* gene was revealed the next year, in 1995 [2]. *BRCA1* and *BRCA2* are classic deoxyribonucleic acid (DNA) stabilizing, tumor-suppressor genes that repair breaks in double-stranded DNA. Now, twenty years later, we can summarize the scientific values of this discovery and its consequences for breast cancer prevention and treatment today.

Inherited mutations in *BRCA1* or *BRCA2* genes predispose to breast, ovarian, and other cancers. Their ubiquitously expressed protein products are implicated in processes fundamental to all cells, including DNA repair and recombination, checkpoint control of cell cycle, and transcription [3]. *BRCA* gene mutations lead to a defect of DNA double-strand break repair through homologous recombination. Disruption of *BRCA* proteins in mutation carriers can induce susceptibility to specific types of cancer [4]. However, the so-called safeguard activities of *BRCA1* gene do not appear to be cell-type specific. Thus, they do not, by themselves, fully elucidate the strong association of *BRCA1* gene mutations with specific cancer types, such as breast cancer.

The incidence of hereditary breast and ovarian cancers reveals close correlation with *BRCA* mutations [5]. *BRCA1/BRCA2* mutations are responsible for 3-8% of all breast cancer cases, whereas for 30-40% of familial cases. Ten percent of patients with ovarian cancer have a genetic predisposition. About 80% of families with a history of ovarian cancer have mutations in the *BRCA1*, while 15% in the *BRCA2* gene. These correlations suggest strong parallelism between the initiations of breast and ovarian cancers, which female organs are mistakenly regarded as being highly endangered by increased endogenous estrogen levels [6,7]. Poorly differentiated triple negative breast cancers (TNBCs) were first characterized in the literature in 2005 by the absence of steroid receptors for estrogen (ER) and progesterone (PR) as well as the lack of tyrosine kinase human epidermal growth factor receptor 2 (HER-2) [8]. Clinically, TNBCs exhibit fairly aggressive local growth, rapid progression and account for a high rate of early metastases, most commonly to visceral organs and central nervous system [9]. Among women with germline *BRCA1* mutation near 50% of breast cancers is triple negative presenting with a high grade histologically [10,11]. Among women with breast cancer, TNBC was established in 57.1% of *BRCA1*-mutation positive and in 23.3% of *BRCA2*-mutation positive cases, whereas in only 13.8% of *BRCA* negative women [12].

Strong correlation between *BRCA* gene mutations and the high risk of TNBC proposes certain mediators between germline mutations and the risk for poorly differentiated breast cancers.

INTERACTIONS BETWEEN ENDOGENOUS ESTROGENS AND WELL FUNCTIONING, WILD *BRCA* GENES

Wild type *BRCA1* gene expression is strongly enhanced during puberty and pregnancy, when estrogen levels exhibit a dramatic increase and an excessive development of mammary

gland takes place [13,14,15]. These observations suggest that high estrogen levels might strongly stimulate the expression of DNA stabilizing *BRCA* genes [16]. Since during pregnancy, the explosion-like cell proliferation in the female organs and fetal structures is associated with extreme increase in estrogen levels, the concomitantly elevated expression of the *BRCA1* gene may serve as a strict safeguard of abrupt DNA synthesis and mitotic activity.

In the mammary gland of ovariectomized mice, estradiol administration increased the level of *BRCA1* expression [13]. Further studies on ER-positive MCF-7 and BT20T human breast cancer cell lines indicated that depletion of estrogens significantly reduced *BRCA1* mRNA expression, and the expression was increased again by treatment with estradiol [17,18]. In *BRCA* proficient human breast cancer cell lines, increased *BRCA1* mRNA expression by estradiol administration suggests that proper estrogen exposure induces apoptosis or differentiation of tumor cells by quick DNA repair and recombination.

Evidences support that estrogen-induced activation of the normal *BRCA1* gene may be important in protecting the breast against cancer initiation. The phytoestrogen genistein, a major active component in soy products, may reduce the risk of premenopausal breast cancer development [19], and increases the expression of *BRCA1* gene in human breast cancer cells in culture [20]. Besides weakly estrogenic genistein, estrogens may also up-regulate the *BRCA1* gene and reduce breast cancer risk. In animal models before the onset of puberty, administration of 17 β estradiol reduced the later risk of breast cancer by the increased expression of *BRCA1* gene [21].

Clinical and experimental data support the cancer preventive and curative impacts of estrogens by means of the augmented DNA stabilizing effect of the increased *BRCA1* gene expression. By contrast, estrogen depletion or defective estrogen signaling may induce cancer initiation and even tumor dedifferentiation attributed to low expression of DNA stabilizer *BRCA1* gene.

DEFECTIVE ESTROGEN SIGNALING ASSOCIATED WITH *BRCA* GENE MUTATIONS

While many specific roles of *BRCA1* gene remain to be clarified, it is clear that functional *BRCA1* protein is required to prevent the malignant transformation of breast cells [15]. Selective inactivation of *BRCA1* gene in mammary epithelial cells results in blunted ductal development, breast hyperplasia, as well as tumor formation [22]. In the breast of *BRCA1* mutation carrier women, the persistent presence of least differentiated type 1 lobules is a characteristic finding [23], suggesting that functional *BRCA1* is necessary for proper estrogen signaling and normal mammary lobular differentiation.

BRCA gene mutation carrier women frequently exhibit the clinical symptoms of estrogen deficiency, such as anovulatory infertility and ovarian failure [24,25,26], in spite of their elevated estrogen levels. By contrast, in certain premenopausal cases with *BRCA* gene mutation, the defects of ER signaling are clinically disguised by reactively increased estrogen synthesis and/or other compensatory mechanisms. With ageing, however, the relatively higher but decreasing estradiol levels are not enough for the breakthrough of ER signal transduction defects and these women have a lifelong increased risk for breast cancer [27].

Since both germline mutations in *BRCA* genes and anovulatory infertility are associated with high susceptibility for breast and ovarian cancers, correlations between *BRCA1* mutation and low response to fertility treatments were examined [24]. In *BRCA1* mutation positive women, the low response rate of ovaries to fertility treatment was significantly increased (33.3%) as compared with *BRCA1* mutation negative patients (3.3%). These results support that *BRCA1* mutations are associated with defective estrogen signaling reflected by an increased rate of ovulatory failure.

In women with *BRCA1/2* mutations, ovarian failure leads to earlier age at natural menopause (under the age of 40) and it was a significantly more frequent observation than among mutation-free cases ($p < 0.001$) [25,26]. The high risk of premature ovarian failure among *BRCA1/2* mutation carriers reflects the disturbances in estrogen synthesis or estrogen receptor signaling pathways. Disorders of estrogen signaling may confer the risk of tumors associated with *BRCA1/2* mutation [27,28].

DECREASED ER-ALPHA EXPRESSION IN CELLS WITH *BRCA* GENE MUTATION

Estrogens, estrogen receptors and *BRCA* genes are in strict crosstalk and interplay in order to maintain cellular health. In *BRCA* gene mutation carrier women, difficulties in estrogen signaling may be associated with the fairly decreased cellular ER-alpha expression.

Molecular basis of the failure of ER-alpha expression was studied in *BRCA* mutant cells. In the breast of women with *BRCA1* gene mutation, low ER-alpha expression and the associated decrease in estrogen signaling may explain the persistent presence of the least differentiated type 1 lobules [23]. *ESR1* gene expression was found to be 5.4-fold lower in *BRCA1*-mutant tumors than in *BRCA* gene proficient ones [29]. These findings suggest that a deficient *BRCA1* gene may cause decreased ER-alpha expression in both developing mammary glands and breast cancers. In patients with *BRCA1* gene defect, the loss of ER expression leads to the predominance of poorly differentiated breast cancers [30], which may be attributed to the decreased estrogen surveillance [28].

Breast tumors in *BRCA1* mutant cases are typically ER α -negative, whereas the majority of sporadic, ER-positive breast cancers express wild-type *BRCA1* [10]. These observations suggest causal associations between *BRCA1* mutation-linked breast cancer and low *ESR1* gene expression.

Considering that in *BRCA* gene deficient cases the crucial compensatory mechanisms are the restoration and nursing of sufficient ER signal transduction, it becomes obvious that selective ER α blockers seriously aggravate the emergency situation of low *ESR1* and ER expressions.

DECREASED ESTRADIOL-LIGANDED TRANSCRIPTIONAL ACTIVITY OF ERS IN *BRCA* GENE DEFICIENT CELLS

The *BRCA1* gene is regarded as an inhibitor of the transcriptional activity of ER-alpha in human breast cancer cells lines [31]. Even recent publications mistakenly established that

BRCA1 defect deliberates estrogen-induced DNA damage resulting in genomic instability and strong risk for tumor formation in highly estrogen regulated tissues [32].

Nevertheless, direct interaction between *BRCA1* protein and the transcriptional activity of ERs is a complex regulatory process. Inhibition of ER-alpha activity by *BRCA1* was demonstrated either in cell lines with endogenous wild type *BRCA1* or in a breast cancer cell line that has defective *BRCA1* [33]. The *BRCA1* protein was found to bind with ER-alpha in vivo and in vitro, by an estrogen independent interaction that mapped to the amino-terminal region of *BRCA1*. *BRCA1* proteins containing the amino-terminal binding with ER-alpha region lost their inhibitory effect on ER-alpha activity. These findings suggest that the amino-terminus of *BRCA1* protein positively interacts with ER-alpha, while the carboxyl-terminus of *BRCA1* may function as a simple transcriptional repression domain [33]. In conclusion, *BRCA1* gene may ambiguously regulate ER-alpha activity, depending on the momentary necessities.

Further studies established that *BRCA1* gene is upregulated in response to estradiol in mammary epithelial cells, and *BRCA1* in turn positively regulates the transcriptional activity of ERs. This implies the existence of a positive feedback mechanism that regulates functional interaction between *BRCA1* gene and ER-alpha in breast cancer cells [18].

In conclusion, *BRCA1* regulates ER expression positively; hence loss of *BRCA1* function may lead to ER-negative phenotype providing a molecular basis for the loss of ER expression in the majority of *BRCA1* mutant cancers [29].

There is a physiologic link between *BRCA1* gene and mammary gland development. *BRCA1* up-regulation is required for controlled proliferation and differentiation of breast cells in puberty and pregnancy [34], while loss of *BRCA1* results in impaired differentiation but increased poorly controlled proliferation in human mammary epithelial cell line [35].

In conclusion, the experienced controversial interactions between *BRCA1* gene and ER transcriptional activity may be attributed to the existence of a balanced feedback mechanism, which serves as a safeguard of healthy mammary cells in every phase of proliferative and resting periods. In breast cancer cells, active *BRCA1* gene and *BRCA* protein increase both the expression and transcriptional activity of ERs resulting in a progressive differentiation and even apoptotic death of tumor cells. *BRCA1* gene defect destroys the defensive transcriptional activity of ER signaling against mutant breast cancer cells, deliberating the initiation and progression of malignancies.

DEFENSIVE COUNTERACTIONS AGAINST BRCA GENE DEFECTS

Although *BRCA* gene mutation carrier women have an increased lifelong risk for cancer development, certain defensive counteractions may help to improve the safeguard of cell proliferation resulting in a tumor-free life.

Increased Aromatase Activity Associated with BRCA Gene Mutation

Transcriptional regulation of target genes is an important function of the *BRCA1* gene [36]. One of its target genes is aromatase CYP19A1, regulating the expression of aromatase enzyme that catalyses the conversion of C₁₉ steroids into bioactive estrogens [37]. In vitro studies

demonstrated the direct binding of *BRCA1* gene to the proximal promoter region of CYP19A1 gene (promoter II) in breast adipose fibroblasts and as a consequence the repression of transcriptional activity [38]. This finding was erroneously evaluated as a defensive mechanism against the danger of elevated estrogen synthesis, while both repression and activation are important players in balanced regulation.

Conversely, gene silencing of *BRCA1* seemed to be associated with deliberation of aromatase gene expression in human stromal adipose cells resulting in increased enzyme activity [39].

These observations suggest that defective *BRCA1* gene reactively induces excessive estrogen synthesis; however, the increased hormone level was erroneously regarded as causal factor of the cancers of breast and ovary.

Aromatase expression was significantly higher in *BRCA1* mutation carriers, either in patients who had experienced breast cancer or in women who had a high risk for breast cancer and had prophylactic removal of their breast tissue [36]. Increases in aromatase and its proximal promoter I.3/II transcripts were also observed in these *BRCA1* mutation carriers, supporting the hypothesis that with decreased *BRCA1* function there is an overregulation of aromatase transcription leading to excessive estrogen synthesis. Lack of functional *BRCA1* protein correlated to higher aromatase levels in 85% of *BRCA1* mutation carriers. The authors erroneously concluded that the link between defective *BRCA1* protein and increased aromatase activity is significant in terms of understanding why carcinogenesis is concentrated to estrogen-producing tissues in *BRCA1* mutation carriers.

Measurements of aromatase activity in the different quadrants of mastectomy specimens from patients with breast cancer indicated that activity was always higher in quadrants associated with tumor as compared with non-involved quadrants. In sequential biopsies of large primary tumors, the measurement of in vitro aromatase content before and during treatment with aminoglutethimide-hydrocortisone showed a marked but apparently paradoxical rise in enzyme activity following therapy [40]. These results may be estimated as the importance of local estrogen synthesis within the breast in terms of both the natural history and behavior of breast cancers.

BRCA1 gene mutation is associated with a combination of excessive aromatase expression and activity, predominantly in estrogen receptor negative phenotypes of tumors [30]. This link between excessive tissular aromatase synthesis and the development of poorly differentiated breast cancer is usually regarded as a justification of the carcinogenic impact of increased local estrogen level.

Nevertheless, in young breast cancer cases (<40 yrs.), locoregional control after breast conserving surgery highlighted that the absence of CYP19-aromatase activity in removed tumor samples carried a strongly significant risk for locoregional tumor recurrence and prophesied poor prognosis [41]. Lack of intratumoral estrogen synthesis seems to be strongly associated with low differentiation of breast cancers, and at the same time tumor growth and rapid tumor spread [28,42].

Prophylactic or therapeutic use of aromatase inhibitors in women with high breast and ovarian cancer risk fairly jeopardizes the health of female organs exhibiting intense defensive estrogen synthesis.

Hyperestrogenism as Compensatory Mechanism in Women with BRCA Gene Mutation

Characteristic high aromatase activity in women with *BRCA1* mutation harmonizes with the consequent finding of reactively increased estrogen concentration. Elevated estrogen synthesis counteracts decreased ER α expression so as to preserve cellular estrogen surveillance.

Excessive estrogen synthesis seems to be an effective counteraction against decreased ER expression in women with *BRCA* gene mutation. Higher serum titers of estradiol were measured in *BRCA1/BRCA2* mutation carriers as compared with women who were free of mutations [43]. The authors erroneously concluded that the high penetrance for breast and ovarian cancers or both can be explained by the increased estrogen synthesis in carriers of *BRCA1/BRCA2* mutations, as elevated estradiol level is regarded as a risk factor for these female tumors. Nevertheless, estradiol is beneficial even in sky-high doses and its long lasting reactive overproduction may save the mutation carrier patients from tumor development [27,28].

Stronger hyperestrogenism (71.7 pg/ml) was observed in *BRCA2* mutation carrier patients as compared with the modestly increased estrogen levels of women with *BRCA1* mutations (45.5 pg/ml) and the normal levels in cases without *BRCA* mutation (38.5 pg/ml) [44]. This result erroneously strengthens the practice of antiestrogen treatment in cases with breast cancer. Higher estrogen production in *BRCA2* mutation carriers seems to be an effective counteraction against defective estrogen signal transduction as a mediator of their markedly lower cancer risk, while the moderate estrogen overproduction in *BRCA1* mutation carriers is associated with higher tumor risk.

In *BRCA* gene mutation carriers, elevated estrogen levels associated with high parity, artificial hormonal cycle created by oral contraceptives or estrogen administration may decrease the high cancer risk. Parity in *BRCA1* mutation carriers significantly reduced the risk for ovarian cancer [45], moreover, the risk was reduced with each additional full-term pregnancy in women with germline mutation [46]. Furthermore, parity with its highly elevated estrogen level also seemed to be protective against TNBC, similarly like against the predominant ER-positive tumors [47].

Use of oral contraceptives (OCs) was found to highly reduce the risk of ovarian cancers in women with both *BRCA1* (OR: 0.56) and *BRCA2* mutations (OR: 0.39) [45]. Ovarian cancer risk decreased with each year of long term contraceptive use in women carrying *BRCA1* or *BRCA2* mutations [48]. Protective effect of OC was established as a chemoprevention against ovarian cancers in young women with *BRCA* mutations; whereas the OC associated risk of breast cancer in *BRCA* mutation carriers seemed to be heterogeneous with inconsistent results [49]. Nevertheless, the use of OCs for at least 12 months was associated with strongly decreased breast cancer risk for *BRCA1* mutation carriers (OR: 0.22) [50].

Consumption of phytoestrogen-rich foods such as soy emerged as preventive measure against breast cancer. Soy consumption may be beneficial in early life before puberty or during adolescence, according to results of immigrant and epidemiological studies [19]. In animal experiments, prepubertal administration of 17 β -estradiol reduced the later risk of breast cancer by inducing a persistent up-regulation of *BRCA1* gene [21].

Increased Ligand-Independent Transcriptional Activity in Cells with *BRCA1* Mutation

A relative decrease in estradiol-liganded transcriptional activity of ERs was observed in *BRCA1* gene deficient human ovarian cancer cells [31]. Nevertheless, ER α showed an unexpectedly increased ligand-independent transcriptional activity in cells with *BRCA1* mutation that was not observed in *BRCA1*-proficient cells [51]. The authors mistakenly concluded that normal *BRCA1* gene mediates the repression of the ligand-independent transcription of the estrogen receptors, while *BRCA1* mutation deliberates the overwhelming, harmful estrogen signaling by ligand independent pathways.

Nevertheless, increased estrogen independent stimulation of ERs in *BRCA1*-deficient tumor cells, may be regarded as a counteraction against defective estrogen-dependent ER transcription aiming the restoration of omnipotent estrogen signaling in emergency situations. High risk of cancer may be manifested if the defect of ligand activated ER signal is not supplemented by compensatory non-liganded ER signaling.

In conclusion, *BRCA1* gene mutation seems to increase the risk of breast cancer initiation and progression particularly that of TNBC by the defective ligand activated transcriptional activity of estrogen. In cells with *BRCA1* mutation, the increased non-liganded transcriptional activity of ERs may be a compensatory mechanism for the improvement of estrogen signaling.

HORMONAL RISK FACTORS FOR OVERALL BREAST CANCER AND TNBC

All justified risk factors for poorly differentiated TNBC development seem to be in close correlation with estrogen loss or defective estrogen signaling and further associated metabolic disorders [28]. The question arises whether *BRCA* mutations may lead to breast cancer and preferentially TNBC development by the defect of estrogen signaling or by quite different pathways.

The majority of breast cancer risk factors seem to be common to both ER-positive and ER-negative tumors, including TNBCs [28]. Well known risk factors for overall breast cancer, such as metabolic syndrome, type 2 diabetes, obesity, African-American race and *BRCA* gene mutation all proved to be particularly dangerous for the development of poorly differentiated, ER-negative tumors and TNBCs as well [12,52-58]. Moreover, the stronger the risk factors, the higher the danger of ER-negative breast cancers, included TNBCs, as compared with ER-positive tumors.

Estrogen-related cancer risk seems to be apparently different, even quite inverse concerning ER-positive breast cancers and TNBCs [59]. These controversies suggest that the biologic mechanisms behind the initiation and progression of both TNBCs and non-TNBCs are completely obscure until now.

Correlations between Menopausal Status and TNBC Risk

Literary data strongly support that young age and premenopausal status in women means an equivocally higher incidence rate of TNBCs as compared with older, postmenopausal cases [60-64]. Nevertheless, it is hardly conceivable that TNBC, which is regarded as an apparently hormone independent tumor, would exhibit increased incidence rate at higher, premenopausal estrogen concentrations, while rarely occurs in hormonally challenged postmenopausal women [28].

In a case control study, breast cancers in women less than 40 years of age, exhibited a significantly higher rate of ER-negative tumors (33.8%) as compared with older cases (21.9%), suggesting a disproportional risk for poorly differentiated tumors in the young age group [61]. Nevertheless, the raw numbers of age dependent incidence of breast cancers clearly show a close to twofold increase in ER-negative tumors and an almost fourfold increase in ER-positive tumors with ageing (Table. 1.). All the statistical risk indices, such as odds ratios (ORs), hazard ratios (HRs) and incidence risk ratios (IRRs) are based on the percentage of cancer cases. Consequently, the majority of studies erroneously report on higher TNBC risk among young women, disregarding the low number of overall breast cancer cases among these cases [28].

Table 1. Age related increases in ER-positive and ER-negative breast cancer incidences

Menopausal status	Average age of patients	Number of patients		Percentage of patients	
		ER+ tumors	ER- tumors	ER+ tumors	ER- tumors
Premenopausal cases	35 years	52	26	66.2%	33.8%
Postmenopausal cases	59 years	178	50	78.1%	21.9%

Notes: With ageing, raw number of tumors shows a close to twofold increase in ER-negative subtypes and a much higher – almost fourfold – increase in ER-positive subtypes, while the percentage of ER-negative cancers exhibits a misleading decreasing trend. Data derived from Hartley et al. (ref. 61). Abbreviation: ER, estrogen receptor.

What can the advantageous factor be in young women suppressing strongly the ER-positive and moderately the ER-negative breast cancers? In premenopausal cases, healthy or slightly defective estrogen synthesis supplies the ligands for the available ERs of tumor cells. In case of sufficient estrogen exposure both the initiation and progression of ER-positive breast cancers may be more effectively suppressed as compared with ER-negative tumors [28]. ER negativity of breast cancer is the crucial histochemical marker defining the poorest prognosis of the disease [61,62]. The antitumor capacity of preserved estrogen level in young women may be in correlation with the fact that estrogen is the ligand of ERs in highly differentiated tumors with better prognosis.

Correlations between Reproductive History and the Risk of Different Breast Cancer Subtypes

An additional puzzling phenomenon is the apparently controversial correlation between the risk of TNBC and reproductive factors in women. High TNBC risk in multiparous women with excessive estrogen signaling and low TNBC risk in nulliparous cases with defective

estrogen exposure are strongly supported by literary data [59,65,66]. These correlations are highly embarrassing if one considers the apparent independence of ER-negative tumors from the environmental concentration of estrogens.

High parity shows strong tumor protective effect even against the cancers of highly hormone dependent female organs including overall breast cancer, endometrial and ovarian tumors [67,68]. Recently, a significantly decreased overall cancer risk was reported after ovulation induction and in vitro fertilization assisted childbirth, mainly due to a lower than expected incidence of breast cancer [69].

Parity and particularly multiparity are associated with a decreased risk of the predominant ER-positive breast cancer type [65,70,71]. Among parous women, even the number of births was inversely associated with the risk of ER-positive breast cancer [59]. Among women who had at least four terminated pregnancies, a strongly decreased risk of ER-positive breast cancer was observed as compared with nulliparous cases (OR=0.55) [48].

Conversely, TNBC incidence exhibited an apparently unchanged ratio in parous women [48,64,71], whereas in certain studies even an increased risk of TNBC was reported in multiparous cases [72-74]. In a recent study the number of births was found to be directly associated with the risk of TNBC [75].

Nulliparity is generally in correlation with anovulatory disorders, thus these hormone deficient cases may be regarded as opposite extremes as compared with multiparous women [6]. Delayed first childbirth may also be associated with prolonged defective estrogen synthesis and ovulatory failures. Postpubertal sexual hormone imbalances are frequently associated with definite or prolonged fertility disorders resulting in nulliparity and delayed first childbearing [76] and inducing increased overall breast cancer risk among premenopausal women [77-78]. High overall breast cancer risk in correlation with defective estrogen synthesis and anovulatory disorders justifies the role of physiologic estrogen signaling in preservation of mammary health [6]. Administration of pregnancy mimicking estrogen and progesterone doses to nulliparous women seems to be a useful strategy for protection against breast cancer [79].

Certain studies suggested that nulliparity plays quite inverse role in the risks of ER-positive breast cancer and TNBC as compared with multiparity [66]. Nulliparous status of women was associated with a 35% higher risk of ER-positive breast cancer (HR=1.35), whereas with a 39% lower risk for TNBC (HR=0.61) [75]. Delayed first childbirth was also directly associated with risk for ER-positive cancers, but showed no remarkable effect on the risk of TNBCs [59].

Considering the apparently contradictory results, if women undertake more childbirth they may be exposed to a stronger risk of developing TNBC, conversely, if they remain nulliparous they are exposed to higher risk for ER-positive cancers. So what should they do?

In multiparous women, good fertility associated estrogen supply and excessive estrogen levels during pregnancies strongly and equivocally reduce the development of overall breast cancers and the predominant ER-positive tumors in particular. A plausible explanation is that estrogen, being the specific ligand for ERs, may preferentially block the development and progression of ER-positive cancers. However, its killing capacity against ER-negative cancers is slower and weaker as the specific tumor receptors are missing. In its complexity, in estrogen rich milieu a fairly decreased number and percentage of ER-positive tumors is associated with a moderately decreased number and an unchanged or deceptively increased percentage of ER-negative breast cancers [28].

By contrast, in nulliparous hormonally challenged women, the weakness of estrogen surveillance results in enhanced overall breast cancer risk. The insufficient estrogen supply has

a defective killing capacity even against the predominant, hormone sensitive ER-positive breast cancer cells resulting in an increased number and percentage of surviving ER-positive tumors. The survival possibility for hormonally weakly controlled ER-negative cancers like TNBCs may disproportionately improve and their raw number may be somewhat decreased, while the relative number (percentage) increases [80].

For women who are afraid of developing breast cancer, it is plausible to choose parity either by natural way or by in vitro fertilization to prevent the development of both TNBC and non-TNBC type tumors.

CONCLUSION

Considering the disproportionally lower tumor suppressor impact of estrogens on ER-negative breast cancers, BRCA gene mutation associated defective estrogen signaling may have close correlation with an easier deliberation of mitotic failures and development of poorly differentiated ER-negative tumors. In cases with BRCA gene mutation, increased aromatase activity, elevated estrogen levels and higher ligand-independent transcriptional activity of ERs are defensive endogenous mechanisms so as to improve the defective estrogen surveillance. In high risk women, the key for breast cancer prevention may be the restoration of triangle partnership among estrogens, estrogen receptors and DNA stabilizer BRCA genes.

Chapter 48

GENOTYPE-PHENOTYPE RELATIONSHIPS IN LANGUAGE PROCESSES IN RETT SYNDROME

***Alessandra Falzone, Antonio Gangemi
and Rosa Angela Fabio****

Department of Cognitive Science, University of Messina, Messina, Italy

ABSTRACT

Rett syndrome (RTT) is a neurodevelopmental disorder mainly caused by mutations in the MECP2 gene affecting around 1 in 10,000 female births. Mutations in the MECP2 gene have been associated with the onset of RTT. Clinical manifestations include severe linguistic and motor impairments that are the core of phenotype symptoms. Some patients show a moderate level of conservation of linguistic functions while others lose the use of functional verbal communication. The objectives of the present chapter are to study in depth the latest theoretical approaches to the link between linguistic processes and the specific RTT genotype.

This chapter begins with a theoretical overview on cognitive alterations and then focuses on linguistic specific impairments characterized by the loss of articulation or the production of few functional sounds. A restricted sample shows the presence of verbal speech (Preserved Speech Variant). Renieri et al. (2009) proposed the term “Zappella variant” rather than “preserved speech variant” to describe milder forms of RTT, because other aspects, besides speech, are involved.

The second part proposes a preliminary research which analyses the correlation between linguistic phenotype and specific genotype.

1. INTRODUCTION

Complex diseases are a set of pathologies for which environmental and genetic factors act together to form a phenotypic manifestation and, unlike monogenic diseases, don't present a standard model of Mendelian inheritance. The phenotype of monogenetic diseases can be

* Corresponding Author's Email: rafabio@unime.it.

complex, but in any case, it depends on the action of a single gene, while in a complex disease, different phenotypic components depend on interactions of more genes that interact with each other in an epistatic way. The difficulty in studying these complex pathologies consists in correlating different phenotypic components to a single specific genetic / environmental factor (Elston, 1995).

1.1. Rett Syndrome (RTT)

Rett syndrome is a neurodevelopmental disorder, affecting around 1/10.000 female births.

In 1998, in a study on genetic RTT cases, Xq28, a critically important region was identified. In 1999, the mutational screening of candidate genes in the region allowed the identification of MECP2 as a cause of the standard form. Ten years later, different research studies regarding the causes of RTT variations have also been carried out.

In 2000, it was also shown that the “Zappella Variant” is caused by mutations in the MECP2 gene.

Another study in 2005 demonstrated that a second gene called CDKL5 localised in the X chromosome, is involved in the variant with early onset convulsions.

Recently, the FOXP1 gene, localized in chromosome 14 has been identified as the first autosomal gene associated to RTT, in particular to the congenital variant.

These results demonstrated that RTT presents genetic and clinical heterogeneity and they provide data for molecular bases to understand pathogenic mechanisms of the disease and to establish targeted therapeutic strategies.

1.2. Standard Form of Clinical Features

RTT presents a clinical characteristic course that we can divide into four levels.

Prenatal and perinatal history is normal although, retrospectively, mild factors of the disease as stereotyped occasional movements or dystonic postures can be observed.

After a period of about 6-18 months, females present a developmental arrest (level I, stagnation), followed by a phase of regression (level II). At this level (1-4 years), they lose previously acquired skills as the hand use and verbal communication.

A rapid decline of social interactions, associated with the appearance of autistic traits is also evident. Females manifest involuntary stereotyped movements of the hand such as torsion, “hand washing” as well as bruxism, breathing irregularities such as apneas and hyperventilation. At this level, head growth slows down, which often results in microcephaly (improperly defined acquired microcephaly). At the next level (level III), called “pseudo stagnation” (4-7 years), there is a decrease in autistic symptomatology and an improvement in social interactions, even though the inability to speak, apraxia and manual stereotypies persist.

Scoliosis and somatic underdevelopment becomes more evident and seizures often occur.

The fourth and final level (5-15 years) is characterized by a global progressive deterioration that can extend to the condition of spastic quadriplegia (IV stage of late motor degeneration).

1.3. Clinical Features of Variant Form

In addition to the standard form, five RTT variants that differ in age of onset and severity of symptoms have also been described.

The “Zappella Variant” (Z-RTT) or Preserved speech Variant, described for the first time by Zappella in 1992, is the most common. This variant presents a more favorable clinical course. Differently from standard RTT patients, they typically present a normal head size; kyphoscoliosis is milder and somatic hypoevolution is reduced, sometimes with a trend of being overweight.

During the third stage, patients regain some previously lost skills, such as verbal communication. Some patients are able to say only a few words, while others are also able to communicate with complex sentences. We can observe an improvement in the use of hands, although considerable dyspraxia persists and the classic stereotyped movements are present. Their motor skills improve to the point that some girls are also able to go up and down stairs independently.

In the variant with early onset convulsions, described for the first time by Hanefeld in 1985, the initial period is masked by the onset of convulsions, usually in the form of flexor spasms. The onset of convulsions is accompanied by a delayed psychomotor development. Only later, girls develop the typical features of RTT as manual stereotypies, above all “Hand-Mouth”. Furthermore, the head size, weight and height are normal in most cases.

In the congenital variant, the psychomotor delay is evident from the first months of life, often with hypotonia and early alterations of EEG. In the following months the different levels previously described in the standard syndrome appear and some generalized convulsions can also appear.

The “Forme Frusta” are RTT variants that don’t have the typical features of the disease. Generally, the first level appears later (1-3 years). Females show initial milder symptoms and present a protracted clinical deterioration.

Usually, they retain some form of communication and developmental abnormalities are much less obvious. The classic stereotypes of the hands may be atypical or absent.

The clinical picture become more similar to RTT when these females reach adolescence and adulthood.

There are very few females with a late variant regression. In these cases, the first level is protracted and regression may arise during primary school.

2. GENOTYPE CHARACTERIZATION

Currently, gene MECP2 mutations [Xq28] are found in the majority of cases (90%) of standard Rett and in 30% of cases of atypical Rett. Since there are many clinically documented RETT cases who don’t present the MECP2 mutation, many scientists in this field believe that the pathology is caused by genetic heterogeneity. Between 2004 and 2005 mutations were identified in another gene; CDKLS, situated in the X chromosome near the Xp22 cytogenetic band in subjects affected by an atypical Rett form characterized by the early onset of resistance to the epilepsy drug (Hanfield’s variant). (Weaving et al. (2004); Tao et al. (2004); Scala et al. (2005)).

MECP2 gene was described for the first time in 1992 (Meehan et al. (1992)). MECP2 is situated on the long arm of chromosome X in the vicinity of the cytogenetic band q28 and it is subject to X inactivation (Adler et al. (1995); D'Esposito et al. (1996); Vilain et al. (1996)).

MECP2 gene occupies a part of genomic DNA of about 76 Kb, it is transcribed in telomere – centromero. Though it is expressed ubiquitously, its levels of expression appear to be regulated in manner, tissue and specific development particularly at the neuronal level. (Jung et al. (2003); Balmer et al. (2003); Castelli et al. (2013); Cohen et al. (2003); Kishi et al. (2004); Mullaney et al. (2004); Shahbazian et al. (2002b)).

MECP2 counts four exons that code 2 different isoforms of the protein, indicated as MeCp2, due to alternative splicing of exon 2. The two isoforms MeCp2 therefore differ only at the N terminal. The most abundant isoform, MeCP2B, contain exons 1-3 e 4, isoform Mecp2 A contain exons 2, 3 e 4. (Kriaucionis and Bird (2004); Mnatzakanian et al. (2004)). The portion 3°UTR of exon 4 of this gene is unusually long (approximately 8.5 Kb) and phylogenetically well preserved. (Coy et al. (1999)).

2.1. Mutations in MECP2 Gene

To date, at least 300 different mutations of this gene have been identified. The spectrum of abnormalities identified include missense, nonsense, frameshift mutations, as well as large deletions and duplications of the entire gene.

The MECP2 mutations are distributed along the entire coding sequence of the gene and 70% of alteration attributable to at least 8 variants, all transitions C > T (Lee et al. (2001)), presumably resulting from spontaneous deamination of cytosine residues in the nucleotide level:(c.316C>T, c.397C>T, c. 473C>T, c.502C>T, c.763C>T, c. 808C>T, c. 880C>T, c.916C>T).

2.2. MECP2 Proteine's Structure

MeCp2 protein (Swiss-Prot P51608) is situated in the nucleus and it consists of three functional domains:

- A Methyl-binding domain (MBD), 85 amino acids
- A Transcriptional Repression Domain (TRD) that counts 100 amino acids (amino acids 207 – 310) important in recruiting other components of the repressor complex. (Nan et al. (1997));
- A C – terminal domain, whose function has not yet been characterized.

Protein MeCp2 is part of a complex transcriptional repressor that contains the Sin3A corepressor and histone deacetylase HDAC1 and HDAC2. The functioning model of this complex predicts that MeCP2 repress the transcription through a mechanism that involves the binding to residues and recruitment of co repressor Sin3A and HDACs to change the structure of the chromatin.

MeCP2 recognizes and binds CpG methylated sites present in the promoters of the gene target, HDACs deacetyl histone tails and this consents DNA to wrap itself around nucleosomes causing the compaction of chromatin. In these conditions, the transcriptional machine loses access to the promoter and the genome is no longer transcribed (Jones et al. (1998), Nan et al. (1998)).

Figure 1. Operation model of the protein MecP2. MeCP2 recognizes and binds CpG and, through the recruitment of cofactors SIN3A and HDACs causes deacetylation of histones and thus the compaction of DNA around nucleosomes. In this way, target genes are not transcribed.

3. PHENOTYPES WITH GENE MUTATION MECP2

Protein MeCP2 has a fundamental role in the repression of the transcription of numerous target genes during neuronal differentiation therefore this mechanism would explain why MeCP2 alterations were detected in different phenotypes in subjects of both sexes characterized by neurodevelopmental disorders.

Alterations have been identified in the autistic spectrum, and also in subjects with Angelman syndrome.

In fact, the full range of phenotypes in which alterations in MECP2 may have a pathogenic role remains to be investigated; it can be hypothesized that alterations of this gene are the basis of both diseases with clinical features that fall within the phenotypic Rett spectrum as well as other forms of pervasive developmental disorders.

Knowledge regarding the importance of the involvement of alterations of this gene is essential to understand the role of the MECP2 protein in a complex functional network that underlies the correct neuronal maturation and to understand better the correlation of alteration with specific phenotypes in the Rett syndrome.

More than 200 different mutations of the MECP2 gene have been reported in the Rett Base (IRSA MECP2 Variation Database; but eight mutations (Arg106Trp, Arg133Cys, Thr158Met, Arg168X, Arg255X, Arg270X,

Arg294X, Arg306Cys) affect around 67% of RTT females. A remaining 10% of RTT cases show a large group of C-terminal frameshift mutations.

Several studies have reported genotype-phenotype correlations, but with conflicting results. Most authors reporting data from different cohorts of RTT patients demonstrated that no correlation exists between missense vs. truncating mutations, whereas others reported that the truncating defects are more severe than the missense ones. Studies aimed at comparing mutations affecting the different functional domains share the opinion that defects affecting the C-terminal domain give a milder clinical score. Differences in clustering the mutations, the heterogeneity in the size of the analyzed cohorts, the selected clinical parameters, and variation in the age of the subjects are likely to explain the conflicting results.

Another important factor modulating phenotype expression is the randomization of X-inactivation; when present, it is expected to influence phenotypical severity. Nevertheless, most studies reported that RTT patients' lymphocytes fail to show a skewed X chromosome inactivation (XCI)

Yet, Knudsen found a significant increase of skewed XCI in RTT patients and their mothers. However, the inclusion of this data in genotype-phenotype correlation studies remains controversial because of the bias of tissue mosaicism. In fact, the brain cannot respect the same ratios as those found in the blood or fibroblasts, which are the investigated tissues. Moreover, a role of SNPs and CNVs as modifier elements of phenotype in patients carrying the same MECP2 mutations should be considered.

Given that conflicting findings about genotype-phenotype relationships in RTT are still under discussion, it seems worthwhile to further investigate this relationship in order to overcome some methodological flaws

In a previous study, Fabio et al. (2014) examined the effect of MECP2 mutations on the phenotypic variability within a group of 114 RTT patients, focusing on specific methodological issues. More precisely, the study was performed taking into account what was recommended by Ham et al. (2005) concerning the weak points of the previous studies. Firstly, biases originating from missing data, multiple testing, and age differences were minimized. Secondly, a main new feature was added to this analytic examination of the RTT phenotype, by using the Rett Assessment Rating Scale (R.A.R.S.), a specific instrument devised to measure the intensity of RTT symptoms and to provide a specific RTT behavioral profile. The specific aim of this study was to correlate disease-causing genetic mutations to the variety and intensity of the detailed symptomatic parameters assessed by R.A.R.S. and to provide insights into the effect of MECP2 mutations on RTT phenotype. The results showed that a specific kind of genotypes can be associated with the severity of symptoms showed by RTT patients. On the basis of these results, our study aims at providing a phenotype/genotype correlation in relation to a specific cognitive process, language production and comprehension.

4. LANGUAGE IN RETT SYNDROME

After its nosographical description, RTT was classified among Pervasive Developmental Disorders (APA, 2000), but it has been moved to the genetic disorder category because of its primary ethiology (DSM V, APA 2013).

An evident feature of Rett Syndrome is that the disorder is characterized by severe alteration in motor and speech capabilities that are considered as inclusive diagnostic criteria (Neul et al., 2010).

In particular, the residual linguistic abilities are very different and each individual could manifest various degrees of severity in language production: whereas some RTT patients completely lose their activity in verbal sound production, which is functional to communication, others preserve functional vocal sound and/or words (Budden, 1997; De Bona et al. 2000; Fabio et al., 2009; 2011; 2013; Zappella et al. 2001).

Linguistic deficits typically arise after the regression phase: indeed, RTT females are characterized by a normal language development comparable with a healthy one before the regression phase. They often exhibit babbling and phonological coupling except for the early onset variant.

It has been demonstrated that linguistic competence levels are correlated to the language acquisition stage in which individuals were at the onset of regression (Marschik et al., 2012).

It has been found that residual linguistic capabilities can be considered as an outcome predictor for the syndrome: the greater the verbal ability before regression, the more likely it is that patients can regain speech functionality to communication and interaction during the pseudo-stationary stage.

There are different linguistic phenotype variants in RTT. A restricted sample shows the presence of verbal speech (Preserved Speech Variant). Renieri et al. (2009) proposed the term “Zappella variant” rather than “preserved speech variant” to describe milder forms of RTT, because other aspects, besides speech, are involved. This form presents a less severe clinical condition, i.e., regular skull dimensions and a relevant reduction of epileptic seizures and breathing alterations.

Few studies have evaluated a genotype/phenotype correlation between linguistic residuals and specific genotype. Uchino et al. (2001) tried to correlate the grade of disability in locomotion and that of microcephalus with a language disability in RTT in a preliminary study and after they correlated language RTT to the loci of MECP2 mutation. This correlation was found on the basis of a qualitative evaluation of spoken language.

This study proposes a genotype/linguistic phenotype correlation based on an articulation capability test by a phonetic evaluation test (Fanzago, 1983). Our hypothesis moves off the assumption that linguistic alterations in RTT derive from alterations in breathing and facial-laryngeal muscle's coordination rather than from general motor disease. As a consequence, genotypes producing severe breathing and facial-laryngeal muscles alteration are expected to show a severe linguistic phenotype.

Indeed, girls with RTT show a complex breathing phenotype that could include hypoventilation, hyperventilation, apneic episodes with clusters of arrhythmic breathing, and breath hold terminated by Valsalva maneuvers (Katz et al. 2009). It seems that modifications of subcortical nuclei in the brainstem, which regulate breathing rhythm, are connected to speech motor control.

It is supposed that this relationship is due to the same neurological altered basis: both respiratory capacity and speech are controlled by subcortical nuclei in the brainstem and they are affected in Rett patients (Ogier et al. 2008, Ramirez et al. 2013). Many studies show that the functional integrity of the brainstem respiratory network (Trevvarthen & Daniel, 2005; Katz et al. 2009; Ogier & Katz, 2008) is affected, but to date this aspect has not yet been analyzed for speech. On the other hand, many studies in the normal and neuropsychological population

show that brainstem nuclei (i.e., basal ganglia, pontine reticular nuclei, substantia nigra, central gray of the midbrain, frontal cortex, caudate, putamen, globus pallidus and thalamus (Deguchi et al., 2000; Saito et al., 2001) as well as part of PNS (i.e., spinal trigeminal tract, solitary tract and nucleus) are involved in both breathing control and in language production (Falzone 2014) (Figure 2)

Figure 2. Cortical and subcortical network for language. The subcortical network for language involves the same brainstem nuclei for breathing control and the respiratory rhythm (i.e., basal ganglia, pontine reticular nuclei, substantia nigra, central gray of the midbrain, caudate, putamen, globus pallidus and thalamus (cf. Falzone, Anastasi, Pennisi, 2014).

Furthermore, there's no doubt that the linguistic phenotype of Rs breathing relies on arousal, i.e., breath and speech alterations can be exacerbated if cognitive arousal increases (Katz et al., 2009).

Some studies have shown that girls with RTT have a modified breathing brainstem network (Trevvarthen & Daniel, 2005; Katz et al. 2009; Ogier & Katz, 2008) but no one has correlated this aspect to articulated language alteration in RS.

On the basis of previous research on residual linguistic capacity in RS patients and on the basis of the evaluation of residual communication ability (both comprehension and articulation) (cf. Fabio et al., 2009) real linguistic phenotype to genotype has been correlated.

In order to do this, speech ability has to be evaluated by using the Fanzago test, a phonetic evaluation instrument which follows the typical degree of language acquisition phase in phonological difficulties aspects. After this, the spontaneous production of language sounds and the presence of breathing alteration at baseline condition and during a cognitive task were evaluated. The more arousal rises, the more that breathing alteration is expected to increase. As a result, even speech ability worsens.

5. METHODS

5.1. Participants

Twenty-one girls with a diagnosis of RTT, ranging from age 4 to 31 (mean= 16,34 years, SD=5,98), took part in the experiment. Their families had been contacted by the Italian Rett Association, which asked them to participate in the study. Twenty girls were met in Tuscany during a summer campus organized by the Association and one girl's parents were interviewed at the Hospital of the Messina University Hospital. According to the paperwork provided by the parents, all the patients examined for MECP2 mutations were positive. All of the participants were diagnosed with Rett Syndrome following both the guidelines established by the Criteria Work Group and the mutation analysis of the methyl-CpG binding protein 2 gene.

A general assessment was carried out by a psychologist through the Vineland Adaptive Behavior Scale (VABS) (Sparrow, Balla, & Cicchetti, 1984), the standardized test for the Rett Assessment Rating Scale (RARS, Fabio et al., 2005) and Modified Colored Progressive Matrices.

The Fanzago phonetic articulation test was administered to evaluate the status of vocal sound articulation and objective production articulated voice functional to communication.

During the cognitive assessment, behavioural breathing parameters were evaluated in order to verify the presence of hypoventilation, hyperventilation, apnea, and breath hold. All the girls showed breathing alteration and none required any Valsalva maneuvers.

5.2. Material

Functional scales. The Vineland Adaptive Behavior Scales are used to diagnose intellectual and developmental disabilities. The Scales are organized into four domains: Communication (Receptive, Expressive, Written); Daily Living (Personal, Domestic, Community); Socialization (Interpersonal Relationships, Play and Leisure Time, Coping Skills); and Motor Skills (Gross, Fine).

The Rett Assessment Rating Scale (RARS) is a standardized scale used to evaluate subjects with Rett's syndrome (Fabio et al., 2005). It is constructed by following the diagnostic criteria for RTT proposed by DSM-IV-TR (APA, 2010) and recent research and clinical experience. It follows a structure similar to that used for the diagnosis of the pervasive developmental disorders included in the same nosographical category as RTT (i.e., Childhood Autism Rating Scale, CARS).

A total of 31 items was generated as representatives of the profile of RTT. Each item concerns a specific phenotypic characteristic and describes four increasing levels of severity. Each item is provided with a brief glossary explaining its meaning in a few words. Each item is rated on a 4-point scale, where 1 = within normal limits, 2 = infrequent or low abnormality, 3 = frequent or medium- high abnormality, and 4 = strong abnormality. Intermediate ratings are possible; for example, an answer between 2 to 3 points is rated as 2.5. For each item, the evaluator circles the number corresponding to the best description of the patient. After a patient has been rated on all 31 items, a total score is computed by summing the individual ratings.

This total score allows the evaluator to identify the level of severity of RTT, conceptualized as a continuum ranging from mild symptoms to heavy deficits.

Cognitive Measures

Modified Raven's Coloured Progressive Matrices were used (Antonietti, Castelli, Fabio, Marchetti, 2003). Differently from the standard Raven's Colored Progressive Matrices (1940), in this adapted scale the A series was administered to girls and each table was larger (42 cm x 29,7 cm). Girls have to choose between two items (one target and one distractor) placed separately in front of them. Both items (target and distractor) were shown 3 times and the spatial position of the target and distractor was randomized. When the girl replied with two consecutive and correct answers the examiner presented the following table; when the girl replied wrongly three times, the test was interrupted.

Linguistic Measures

The Fanzago phonetic articulation test (1983) is used to evaluate the articulation capabilities in children and it is a good measure of their phonetic development. This instrument is based on spontaneous/repetition elicited denomination of 114 figures grouped in 22 tables. Each table represents one image whose name starts with a vocal sound and other objects in which the same sound is placed in a second or third position or is coupled with a vowel or consonant sounds. This study uses items which represent perceptively salient and commonly used objects for RTT.

This test proposes an ontogenetic approach to speech sound production and it groups the phonemes on manner articulation (occlusive, fricative, affricate, nasal, lateral, vibrant).

Target phonemes are reported in a specific template and it's possible to indicate if it has been produced correctly, omitted or distorted. If girls utter the entire word painted in the image during spontaneous or elicited production, it can be marked apart.

Respiratory Evaluation

Breathing parameters were evaluated in order to verify the presence of hypoventilation, hyperventilation, apnea, and breath hold. RTT girls typically present an altered respiratory rhythm. Some studies report alteration during both sleep and when awake. For sleep evaluation, previous respiratory evaluation, the clinical data, and parent reports were used. The respiratory rhythm was measured through behavioural analysis.

All the girls were video taped, two observers independently transcribed the first five minutes of each tape (one during sleep and one in the waking state). The final transcription was then coded independently by both observers for the behavioural breathing parameters. The inter-rater agreement concordance was high (Kappa index = .98).

5.3. Procedure

All the activities were performed in a setting suitable for language activity with patients: all distracting stimuli were removed so the girls focused only on the task.

After the initial assessment, each girl was evaluated at breathing baseline. After the Fanzago test was administered starting with spontaneous vocal production. In the second step girls had to produce phonemes at the request of the linguistic therapist. In this study, girls are requested to produce first vowel sounds, that are easier to articulate and that appear early on during normal development. Then the figures with objects whose name starts with consonants were shown (starting with easier sounds like /p/ /n/ /b/ /m/ and following by more complex ones /r/ /z/). In this study only images with objects starting with phoneme targets were presented, whereas words with phoneme targets in a second or third position were not shown. All correct phoneme (spontaneous/elicited) production was marked on the specific template, in which therapists can write if girls utter the entire word painted in the image during spontaneous or elicited production.

In order to check the effective results of the requested sound production task, the alteration of breathing rhythms during a cognitive, not linguistic task was evaluated in this study.

5.4. Results

Results are presented in relation to both the breathing problems and the language ability.

With reference to the first analysis, the respiratory rhythm was normal during sleep and abnormal in the waking state. To calculate the abnormality of the breathing in the waking state, the sum of each type of respiratory dysfunctions for five minutes was analyzed. With reference to the second analysis, four parameters of the Fanzago test were used: the number of vowels spontaneously produced, the number of consonants spontaneously produced, the number of vowels with elicited denomination and the number of consonants with elicited denomination.

Before proceeding with the analysis of the genotype-phenotype correlation, Pearson's correlation coefficient between the sum of each type of respiratory dysfunctions and the four parameters of Fanzago test were calculated. Results show that breathing problems display an inverse correlation with each of the Fanzago parameters, namely with the number of vowels spontaneously produced ($r(21) = -.378$, $p < .137$), the number of consonants spontaneously produced ($r(21) = -.61$, $p < .001$), the number of vowels with elicited denomination ($r(21) = -.498$, $p < .03$), and the number of consonants with elicited denomination ($r(21) = -.29$, $p < .23$).

To proceed with the genotype-phenotype correlation, since the number of participants was low, dichotomized scores to classify participants into a particular breathing type were used. Based on high ($>$ median) or low ($\leq$ median) scores on respiratory rhythm ($Mdn = 1.2$), mild breathing problems ($Mdn = 0.6$), and severe breathing problems ($Mdn = 2.8$), participants were placed within one of the two type categories. Since some of the girls with RTT shows only clinical features and not mutation in MECP2, only 14 patients were included in the analysis.

As shown in figure 3, patients with a truncating mutation after NLS manifested a lower degree of impairment than patients with a truncating mutation within NLS in the breathing dysfunctions ($\chi^2(2, N = 14) = 1.74$, $p < .05$).

With reference to the second analysis, the genotype-phenotype correlation was carried out with four parameters of the Fanzago test: the number of vowels spontaneously produced, the number of consonants spontaneously produced, the number of vowels with elicited denomination and the number of consonants with elicited denomination. No girl produced single consonants, but consonants together with vowels, i.e., syllables. To calculate these correlations, the sum of each type of syllable and the sum of each type of vowels was

considered. Again, we used dichotomized scores to classify participants into a particular category. Based on high ($>$ median) or low ($\leq$ median) scores on the number of vowels spontaneously produced (Mdn = 2), low level (Mdn = 0.6), and high level (Mdn = 2,8), participants were placed within one of the two type categories. Because some of the girls with RTT show only clinical features and not mutation in MECP2, again, only 14 patients were included in the analysis. As shown in figure 4, patients with a truncating mutation after NLS show a similar pattern to those observed in patients with a truncating mutation within NLS ($p<.48$). Since the Italian language has only 7 vowels (in many regional variations, only 5 with phonological differentiations), it may be that a floor effect does not permit the performances of the girls within each domain to be differentiated.

Figure 3. Genomic structure of the MECP2 gene and localization of breathing problems in the coding regions.

Based on high ($>$ median) or low ($\leq$ median) scores on the number of consonants spontaneously produced (Mdn = 3), low level (Mdn = 1.2), and high level (Mdn = 5,8), participants were placed within one of the two type categories. As can be seen in figure 5, patients with a truncating mutation after NLS show similar pattern to patients with a truncating mutation within NLS ($p<.34$).

With reference to the number of vowels with elicited denomination, based on high ($>$ median) or low ($\leq$ median) scores on respiratory rhythm (Mdn = 1), low level of vowels with elicited Denomination (Mdn = 0.4), and high level of vowels with elicited denomination (Mdn = 2,7), participants were placed within one of the two type categories. As shown in figure 6, patients with a truncating mutation after NLS manifested a higher level of vowels denominations than patients with a truncating mutation within NLS (χ^2 (2, N = 14) = 2.15, $p<.05$). With reference to the number of consonants with elicited denomination (namely the

syllables), only two girls (P376S and T442T) were able to repeat a high number of syllables (respectively 12 and 10). For this reason the relative figure was not produced.

Figure 4. Genomic structure of the MECP2 gene and localization of vowels spontaneously produced in the coding regions.

Figure 5. Genomic structure of the MECP2 gene and localization of syllables spontaneously produced in the coding regions.

Figure 6. Genomic structure of the MECP2 gene and localization of vowels with elicited denomination.

CONCLUSION

In this study, disease-causing mutations have been related to the intensity of the parameters of the breathing problems and the Fanzago test, namely the number of vowels spontaneously produced, the number of syllables spontaneously produced, the number of vowels with elicited denomination and the number of consonants with elicited denomination. Comparisons between the truncating mutations differently affecting functional domains induce support for the idea that the crucial factor that leads to different phenotypes is the integrity of NLS.

As in the study of Fabio et al. (2014) this study supposes that if the protein can penetrate into the nucleus and link to Methylated CpG, it maintains a residual role causing milder clinical damage.

The differential phenotypic effects produced by the two kinds of mutations were clearly shown by the difference in the breathing scores and in the level of the vowels denomination with elicitation.

Our work analyzed samples with a limited number of patients, for this reason it is just a pilot study and more data has to be collected. The most important innovation introduced in the study was the use of the correlation between breathing and language in relation to the specific genotype.

Chapter 49

MARFAN SYNDROME: A RARE AND SOMETIME VERY DISABLING GENETIC DISORDER

Henry J. Mankin and Keith P. Mankin*

Massachusetts General Hospital, Harvard Medical School,
Orthopaedic Department, Boston, MA, US

ABSTRACT

Marfan Syndrome was originally described by Antoine Bernard-Jean Marfan in 1896 and is an uncommon inherited connective tissue abnormality which occurs as an autosomal dominant genetic disorder with frequent mutations.

The patients have normal mentation but have a characteristic increase in height, abnormally long limbs, arachnodactyly, joint hypermobility, distinctive facial features, scoliosis, ectopia lentis, dural ectasia and array of aortic and cardiac abnormalities that are often life threatening. The genetic cause of the disease has been identified. Although some medical and surgical treatments are currently in practice they are not always helpful.

The orthopaedic problems are often significant and sometimes require complex surgical interventions.

INTRODUCTION

Marfan Syndrome originally described by Antoine Bernard-Jean Marfan in 1896 is an uncommon inherited connective tissue abnormality which occurs as an autosomal dominant genetic disorder with frequent mutations. The patients have normal mentation but have as characteristic features excessive height, abnormally long limbs (dolichostenomelia), arachnodactyly (spider-like digits on hands and feet), joint hypermobility, distinctive facial abnormalities, scoliosis, dislocating lenses (ectopia lentis), enlargement of the dural sac (dural

* Dr. Keith Mankin was formerly an active Chair-person in the MGH Pediatric Orthopaedic Division.

ectasia) and an array of aortic and cardiac abnormalities that are frequently life threatening. The nature of the abnormality has been identified and the genetic cause has been discovered. Some medical treatments are currently available to somewhat protect against cardiac disasters and surgical approaches can reduce the risk considerably. The orthopaedic problems can be significant and sometimes require surgical intervention, particularly for spinal or hip abnormalities or fractures.

HISTORY OF MARFAN SYNDROME

Antoine Bernard-Jean Marfan (1858-1942) was born in France and after completing his medical training in Toulouse and some special training in children's diseases, became Chief of Pediatrics at the University of Paris and the Hopital des Enfants Maladies in 1914, a position he held until his retirement in 1928 [19].

He became very involved in defining infectious and other disorders in children and described features of syphilis (Dennie-Marfan syndrome), a red triangle on the tongue characteristic of typhus (Marfan's sign), rachitic epiphyseal swelling of the medial malleous (Marfan's symptom), and a prognostic rule related to tuberculosis of the throat (Marfan's Law) [19]. In 1896, Marfan presented a case of a 5 year old girl, Gabrielle P. to the Societe Medicale des Hopitaux de Paris [37].

He pointed out her disproportionately long limbs, asthenic physique, and slender and exceptionally long fingers and toes. She was studied again with X-rays by Henri Mery and Leon Babonneix in 1902 [41] and they noted scoliosis and thoracic asymmetry; and somewhat later she was discovered to have cardiovascular abnormalities and dislocations of her lenses. Subsequent reports on other patients by Achard in 1902 [1] defined the familial nature of the disease and Salle in 1912 reported necropsy findings of changes in the heart and aorta [62]. In 1914, Boerger first clearly defined ectopia lentis in the patients [10].

It was Weve who in 1931 [77] confirmed the hereditary characteristic of the disease and provided the name "dystrophia mesodermalis congenital, type Marfanis" and since then, the disorder has been known as Marfan syndrome. The cardiac and aortic abnormalities in the patients were further described by Baer, Taussig and Oppenheim in 1943 [5] and shortly thereafter by Etter and Gover (21). Victor A. McKusick became fascinated with the disease and wrote about it extensively beginning in 1955 [28, 39, 40].

Gordon [29] and Schwartz [64] separately in 1962 and 1964 attempted to establish the likelihood that Abraham Lincoln had had Marfan syndrome but despite attempts to seek the gene error in his remains, the issue still remains unclear [28].

GENETIC CAUSATION AND FREQUENCY OF MARFAN SYNDROME

Marfan syndrome is an inherited connective tissue disorder transmitted as an autosomal dominant trait with frequent mutations [7,11,16,25,28,32,40,51]. The disorder is equally distributed in ethnic groups, is slightly more frequent in females than males, and occurs worldwide at 1 per 5-10,000 births [7, 28, 32, 40, 51].

The disorder is now known to be caused by mutations in the fibrillin-1 (FBN1) gene located on chromosome 15q21.1 [11, 15, 16, 28, 56]. The gene encodes the glycoprotein fibrillin which is a major building block for microfibrils including those involved in the skeletal system, the spinal dura, the optic lens supporting system and the elastin in the aorta and cardiac valvular structures [15, 16, 25, 26, 28, 47].

It has also been proposed that there is a disturbance of tissue homeostasis of elastic fibers, increased susceptibility of fibrillin to proteolysis and dysregulation of TGF- β resulting in increased apoptosis [16, 25, 43, 46]. The gene error can be identified not only in patients with the disorder or their family but in uterine fluids.

It is also possible to identify the changes seen in the child in the uterus by appropriate imaging studies [13, 28, 32].

CLINICAL FINDINGS IN PATIENTS WITH MARFAN SYNDROME

Patients with Marfan syndrome may have multiple finding, some frequent and some less commonly. In 1986, a Committee established the Berlin Criteria, which includes diagnostic features which are commonly present and are required to make the diagnosis (major factors); and others which are less commonly present and may be associated with other disorders [7, 28, 58]. Of some importance in any discussion of Marfan syndrome is a listing of some of the other genetic disorders that may resemble aspects of Marfan syndrome and cause confusion in both diagnosis and treatment protocols. The similar lesions that have some of the characteristics of Marfan syndrome include homocystinuria [28], Ehler's Danlos syndrome [28, 40], Klinefelter syndrome [33, 54, 67], Lujan Fryns syndrome [50], van den Ende-Gupta disease [30, 65], Joubert syndrome [27, 44], Shprintzen-Goldberg syndrome [31, 57, 61], Beals disease [72], Marfanoid hypermobility syndrome [76], Stickler syndrome [8], PHACE syndrome [66] and some other disorders that affect the hands, feet, heart, aorta and bones [6, 21, 27, 28, 40]. The list of findings included in this chapter are considered important only for the diagnosis of Marfan syndrome and hence are known as "major factors" according to the Berlin Criteria [7].

General and Orthopaedic Characteristics of Marfan Syndrome

Most patients with Marfan syndrome have normal mentation [20, 28, 40, 49, 51]. Children born with Marfan syndrome are often quite tall and in a short time are taller than their normal siblings and peers [7, 20, 28, 40, 48] (Figure 1). Some of the patients as adults may grow to over seven-feet in height [20, 32, 48, 49]. An important finding is dolichostenomelia, which is defined as having excessively long limbs, far in excess of the normal relationship of the upper and lower extremities to the rest of the body [28, 40] (Figure 2). The bones are generally osteopenic with frequent fractures [7, 12, 18, 24, 35] and with an unusually frequent occurrence of protrusio acetabulae which can be very disabling [18, 68, 70, 73, 79]. Scoliosis is common (Figure 2). The limbs are excessively thin suggesting that not only are the bones diminished in circumference but that there is less soft tissue surrounding them. The fat content of the soft tissues of the extremities is reduced and there is often muscular underdevelopment so that the extremities are much thinner than those of unaffected individuals [7, 28, 40] (Figure 1).

Figure 1. Patients with Marfan's syndrome are frequently excessively tall and sometimes very thin.

The hands and feet show very thin and much elongated digits which are described as “arachnodactyly”, suggesting that they resemble the limbs of spiders [7, 21, 25, 32, 51] (Figure 2).

Flat feet are common as are dislocations of joints such as the elbows, wrists, knees and especially hips [25, 28, 40] (Figure 2). The great toe is sometimes excessively elongated (Figure 3). The hand digits are excessively mobile and the flexed thumb may extend beyond the four fingers when the hand and digits are flexed (Steinberg Thumb Sign) [28] (Figure 4). In addition the combination of a thin wrist and long digits may allow an overlap of the thumb and first and fifth fingers when the wrist is grasped (Walker-Murdoch Sign) [28] (Figure 5).

Figure 2. Skeletal abnormalities in patients with Marfan's syndrome can be quite excessive and very disturbing to function. The calvarium can be thinner than normal and fingers elongated and distorted in shape. Scoliosis is common. Joint structures are disturbed and the patients may develop arthritic changes.

Figure 3. Elongation of the great toe sometimes occurs and may be very disabling.

Figure 4. The Steinberg Thumb sign a combination of narrow hand, long digits and loose joints permits the thumb to extend well beyond the ulnar surface.

Figure 5. Walker Murdoch sign the digits are so flexible the tips of the fingers may appear in the spaces between the proximal structures in the same joint.

The ribs show abnormal growth and many of the patients show either a pectus excavatum or a pectus carinatum [4, 28, 40]. The limbs may show gross structural distortion resulting in functional loss (Figure 6).

Scoliosis or kyphoscoliosis occurs in 30-60% of the patients, is commonly present in even young children and progresses with advancing years [9, 25, 28, 32, 40, 89] (Figure 2). The lesions along with the pectus changes and facial deformities are such as to compromise pulmonary function in some of the patients and may be associated with sometimes severe sleep apnea [4, 14, 23, 40].

Figure 6. Bowing of the distal extremities may make it difficult for the patient to walk.

Additional findings include spina bifida occulta, hemivertebra, cleft or high-arched palate and dental crowding [9, 40] and a thin narrow face and prognathism is characteristic [9, 25, 28, 32] (Figure 1). One of the more common entities is dural ectasia in which the dura becomes moderately or markedly expanded causing widening of the spinal canal, thinning of the vertebral cortex and pedicles, dilatation of the neural foramina and protrusion of the dura outside the bony canal [2, 3, 7, 9, 22, 52, 71, 73, 75]. These findings may cause loss of nerve function and even paraplegia. Many of the patients are muscularly impaired so cannot perform exercises or participate in sports [12, 20, 40, 49, 74].

Ocular findings: Almost all patients with Marfan syndrome have ocular findings and often complaints related to visual alterations and loss. The most frequent problem is “ectopia lentis”, partial or complete dislocation of the lens, which occurs in 50 to 80% of the patients [6, 28, 38, 40, 51]. Tremor of the iris may occur and suggests the likelihood of dislocating lenses. Flattening of the cornea is common and blue sclerae have been reported in patients with the disease and visual loss is common [28, 38, 40]. Many of the patients have myopia and loss of visual acuity which requires glasses. Occasional cases of retinal detachment are encountered and blindness is not unusual in these patients.

Despite normal intelligence some of the patients have considerable difficulty in a school setting because of inability to read either small print or a distant blackboard [38, 49, 74].

Cardiovascular disorders: Seventy percent of the patients with Marfan syndrome have aortic root dilatation and aortic regurgitation [5, 27, 28, 32, 39, 40, 51, 53].

The process may be manifest at an early age and is more common in men than in women [6, 27, 28, 39, 40]. A diastolic murmur over the aortic valve may be present [28].

Aortic dissection involving the ascending aorta is a serious problem and can lead to the death of the patient. Mitral valve prolapse may occur in 55-70% of the patients and results in a high-pitched late-systolic murmur, shortness of breath and a rapid pulse rate [6, 28, 39, 40]. Pulmonary artery dilatation may also occur and even a dissecting aneurysm of the pulmonary artery which can be fatal [6, 28, 51, 53].

Most of these can be diagnosed by electrocardiography, echocardiography and MRI studies of the heart and the aorta and these studies should be done regularly.

In addition some patients have been found to have other cardiovascular manifestations, including coarctation of the aorta, patent ductus arteriosus, absent pulmonary valve and interatrial stenosis [28, 40, 51, 53]. Patients may develop spontaneous pneumothorax or apical blebs (23,28). Cardiac and aortic disorders are serious and can lead to the patient's death, often unexpectedly and at an early age or even in partum [13, 27, 28, 39, 45, 53, 63].

Other findings: These include unusual skin changes such as striae atrophicae (transverse striations often located in the back). Some of the patients may have spontaneous or incisional herniae. [28, 40].

DIAGNOSTIC STUDIES FOR THE STUDY OF PATIENTS SUSPECTED OF HAVING MARFAN SYNDROME

As indicated above, family history is an essential part of the evaluation of the patient. Studies for the molecular gene error seeking the FBN1 mutation are important to provide a competent system of diagnosis of the disease. Similar studies seeking the genetic error in the patient's parents and siblings may also be helpful [11, 15, 28, 40, 47].

All children or adults thought to have Marfan syndrome should be evaluated by a team of clinicians which includes individuals interested in genetic diseases, orthopaedic disorders, ocular problems and cardiac diseases. Both children and adults require imaging studies which includes the spine, pelvis, limbs, hands, feet, chest, skull, heart and lungs. Some of these should be done regularly. CT and MRI imaging are particularly important in the study of the spine for dural ectasia [2, 3, 22, 71, 75]. Bone densitometry should be performed at least yearly for all patients [24, 35]. Frequent evaluation of the heart sounds by a competent cardiologist and echocardiography, electrocardiography and MRI may be useful and life-saving [28, 32, 39, 40, 47, 51]. Ocular studies should include slit-lamp evaluation and keratometry [28, 38].

TREATMENT OF PATIENTS WITH MARFAN SYNDROME

Some of the patients with Marfan syndrome may require no treatment other than frequent observation for ocular, cardiac or orthopaedic complaints or findings. The majority however do require some attempts to alter the progress of the disease and not only keep the patients alive but try to improve their life status.

Medical treatment: Recently, beta-blockers have been introduced to reduce the cardiac and aortic stress and hopefully reduce some of the commonly developing problems [28, 32, 55, 59, 78]. The drugs include atenolol, propranolol hydrochloride and verapamil hydrochloride. Estrogen and androgen and somatostatin have been administered to children to slow their skeletal progression but at this point has only limited success and may produce additional problems [28, 48, 60].

Cardiac treatment: Supportive cardiac measures may be helpful but for some patients [42, 47]. For patients whose lives are threatened, surgery for aortic or mitral valve repair or replacement, aortic arch reconstruction or composite aortic graft insertion or replacement may

be required [28, 42, 47, 53]. A recent report suggests that cardiac transplantation is necessary for some patients [34].

Ocular treatment: Myopia is treatable with refraction and lens defects are best treated by surgical procedures [22, 38].

Orthopaedic treatment: Bracing of spinal curvature may be helpful and prevent progression of scoliotic and kyphotic changes. It may be necessary to do corrective surgery especially if the patient develops dural ectasia or progressive scoliotic deformity [17, 36, 42, 69, 71]. Pectus excavatum if severe may require surgery to prevent damage to the pulmonary tree and the aorta [28, 40]. Surgery to correct protrusion acetabulae is sometimes necessary but may not be effective [70, 73, 79]. Surgery for hands, feet, elbows, hips or knees are occasionally necessary for subluxations or fractures. The use of bisphosphonates in an attempt to decrease the osteopenia of bony segments and reduce the likelihood of fractures may be tried but as yet has not been reported to be successful [24, 28].

Psychological treatment: It should be apparent that the patients with Marfan syndrome and their families have a great burden in their lives [49, 74]. The children are tall and unusually structured and considered strange in appearance by normal persons. The development of eye problems sometimes limits their ability to be educated and their physical problems markedly limit their ability to participate in social and athletic activities. The patients and their parents may need psychiatric support and they should also consult with geneticists about issues related to having additional children.

DISCUSSION

Professor Marfan first described his patient Gabrielle P. in 1896 and we have over the years since then, gathered some additional information about the clinical characteristics of the disease and the sometimes life and limb threatening complications. We now know the genetic origin of the process and how it causes the disorder and this is very helpful in diagnosis and familial evaluation. We have cataloged the frequency of the various symptoms and signs and established their value in providing criteria for diagnosis. We have also begun a series of medical and surgical protocols for management of these patients but at least thus far, they really cannot reverse the process they can only treat the complications. It is hoped that over the next decade that we can define how best to treat the genetic error, possibly in utero after the diagnosis is made and thus reduce the effect of this sometimes devastating disorder.

Chapter 50

MARFAN SYNDROME AND PERIODONTITIS

Jun-ichi Suzuki^{1,*} and Yasunobu Hirata²

¹Department of Advanced Clinical Science and
Therapeutics, The University of Tokyo, Tokyo, Japan

²Tokyo Teishin Hospital, Tokyo, Japan

ABSTRACT

Marfan syndrome (MFS) is a systemic connective tissue disorder that is caused by mutations in the extracellular matrix protein fibrillin-1. While MFS is considered to be at high risk of dental disorders and cardiovascular disease (CVD), little causal relationship has been provided to date. In this article, we reviewed the prevalence of periodontitis in patients with MFS to assess the relationship between periodontal bacterial burden and CVD in MFS patients.

1. MARFAN SYNDROME: A SYSTEMIC CONNECTIVE TISSUE DISORDER

Marfan syndrome (MFS) is an autosomal dominant disorder affecting the connective tissues [1]. Mutations in the fibrillin-1 gene are responsible for alterations of the glycoprotein fibrillin-1, which is a component of the microfibrils in the connective tissue matrices [2]. These microfibrils were included in the suspensory ligament of the lens, skeletal system, lungs, blood vessels and skin [3]. Thus, MFS is a systemic disease where the localization and degree of symptoms are individually different [4].

Cardiovascular complications, especially aortic dissection or ruptures, are the major cause of morbidity and mortality [5].

* Corresponding Author's Email: junichisuzuki-circ@umin.ac.jp (The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8655, Japan. Tel: 81-3-5800-9116; Fax: 81-3-5800-9182).

MFS relies on defined clinical criteria (Ghent nosology) that were outlined to facilitate accurate recognition of this genetic syndrome. The Ghent criteria comprise of a set of major and minor manifestations in different body systems.

Recently, an international expert panel established a revised Ghent nosology that puts more weight on cardiovascular manifestations [6].

In addition to the systemic manifestations, MFS sometimes exhibits characteristic oral features including maxillary protrusion, high palate, crowded teeth and fragility of the temporomandibular joint [7].

However, detailed characteristics of oral features including periodontitis in MFS are still to be elucidated.

2. PERIODONTITIS: AN ORAL CONNECTIVE TISSUE DISORDER

Periodontitis is one of the most common chronic infectious diseases in humans. Pathologically, periodontitis is characterized by gingival inflammation and the loss of periodontal support tissue [8]. Periodontopathic bacteria generate host immunological inflammatory responses, thus resulting in the secretion of cytokines and matrix metalloproteinases (MMPs) [9]. This leads to the extracellular matrix destruction of the periodontal tissues [10] resulting in connective tissue disorder.

In patients with periodontitis, several inflammatory factors increase [11], meaning that systemic inflammation can be caused by periodontal infection. A strong association between dental disease and cardiovascular diseases has been demonstrated [12, 13].

Especially, periodontal disease has been reported to be an independent risk factor for cardiovascular disease [14]. Previous studies also revealed a deep relationship between periodontal diseases and abdominal aortic aneurysm (AAA) [15, 16]. Clinical investigations demonstrated that some periodontal pathogens accelerated the progression of AAA [17].

Recently, we demonstrated the pathophysiological and epidemiological relationship between specific periodontal pathogens and AAA using experimental [18-20] and clinical studies [21, 22].

3. TGF- β IS A COMMON CRITICAL FACTOR IN MFS AND PERIODONTITIS

It is well known that the elevated level of the active TGF- β in the plasma is major manifestations of MFS. Chaudhry et al. [23] demonstrated that mutation of fibrillin 1 altered intercellular communication and significantly increased TGF- β protein level in the extracellular space. TGF- β is a paracrine regulatory molecule of several processes [24].

It also enhanced collagen production and extracellular matrix (ECM) remodeling. TGF- β is produced in dimer form in the cells and is being bound with latency-associated protein (LAP) to form small latent complex (SLC). This secreted SLC is bound extracellularly to latent TGF- β binding protein (LTBP) to form large latent complex (LLC). In MFS, fibrillin 1 mutation occurs, and LLC becomes unable to attach to microfibrils. Latent form is not generated,

resulting in elevated serum TGF- β level. TGF- β joins to its dimer receptor forming a complex that induces the phosphorylation cascade [25].

In periodontitis patients, TGF- β levels were also significantly elevated in serum and saliva compared to controls [26].

It was reported that a periodontal pathogen, *Porphyromonas gingivalis* (*P.g.*) invaded aortic smooth muscle cells (SMCs) and activated TGF- β and Notch signaling pathways. These findings support the association between periodontitis and cardiovascular diseases [27].

Thus, TGF- β in saliva may serve to predict the progression of periodontitis and associated systemic inflammatory diseases.

4. CLINICAL OBSERVATION OF PERIODONTITIS IN MFS PATIENTS

De Coster et al. revealed that severe and frequent oral manifestations were observed in patients with MFS. Local hypoplastic enamel spots, root deformity, abnormal pulp shape, pulpal inclusions, calculus and gingival indices were frequent findings in MFS patients [28].

Although severe periodontitis is sometimes observed in MFS patients, little information was provided to show its morbidity in MFS patients. Judge et al. showed that individuals with MFS were at high risk of developing dental disorders [29].

However, there has been no report to reveal the severity and frequency of periodontitis in MFS patients.

Thus, we revealed the incidence and severity of periodontitis in Marfan syndrome patients [30]. The subjects were patients with MFS (n=40) and age and gender matched healthy individuals (n=14) were employed as a control group. Full-mouth clinical measurements, including number of teeth, probing of pocket depth (PD), bleeding on probing (BOP) and community periodontal index (CPI) were recorded. We revealed that MFS patients had periodontitis (CPI grade 3 and 4) more frequently than the age and gender matched control subjects.

Furthermore, MFS patients had significantly more severe periodontitis and fewer remaining teeth compared to the controls. We concluded that a high incidence of periodontitis was observed in Japanese MFS patients.

Next, we analyzed periodontitis in cardiovascular disease (CVD) patients with or without Marfan syndrome [31]. In this clinical investigation, we analyzed periodontal condition and periodontopathic pathogens. The subjects were MFS patients with CVD (n=47); age and gender matched non-MFS CVD patients (n=48) were employed as controls. Full-mouth clinical measurements and the existence of three periodontal pathogens, *Porphyromonas gingivalis*, *Aggregatibacter actinomycetemcomitans*, and *Prevotella intermedia* were measured. We revealed that MFS patients had periodontitis more frequently than the age and gender matched non-MFS control subjects. MFS patients had significantly severer periodontitis, fewer remaining teeth and deeper PD compared to the non-MFS controls.

Furthermore, the serum antibody titer level against *Prevotella intermedia* was significantly lower in MFS patients compared to the non-MFS patients.

CONCLUSION

We concluded that periodontitis might influence the pathophysiology of MFS. Periodontal pathogens might be a therapeutic target to prevent CVD development in MFS patients.

COMBINED PECTUS CORRECTION AND AORTIC VALVE SPARING ROOT REPLACEMENT IN MARFAN PATIENTS

Jean-Philippe Verhoye* and Jacques Tomasi

Department of Thoracic and Cardio-Vascular Surgery,
University Hospital of Rennes, rue Henri Le-Guilloux, Rennes, France

ABSTRACT

Introduction: Pectus deformities can coexist with cardiovascular diseases. This association is well known in tissue conjonctive disorders such as Marfan's syndrom. Combined procedures can be performed safely and represent an interesting alternative in such situations.

Valve sparing aortic root replacement has excellent long term outcomes and has become an increasingly popular alternative to aortic root replacement especially in young marfan patients to avoid lifelong anticoagulation.

We present our serie of single-stage pectus correction and cardiac surgery, and emphasize the role of aortic valve sparing interventions in such situations by a review of the literature.

Methods: A retrospective review was conducted of patients who underwent chest deformity repair and cardiac surgery at the same time from January 2007 to May 2014. All datas were collected propestively in our data base.

A review of literature was conducted to collect all published cases of combined valve sparing root replacement and correction of a chest wall deformity.

Results: Including our serie (4 patients) 12 patients underwent a combined Tirone David and chest wall deformity correction. 10 patients underwent a Nuss procedure, 2 patients a modified Ravitch procedure.

Conclusion: Combined technique of valve sparing aortic root replacement and correction of a chest wall deformity especially by Nuss technique is safe and effective. This strategy has excellent mid-term results for both aortic and chest wall pathologies.

Keywords: Marfan syndrom, pectus, aortic valve sparing

Chest wall deformities and congenital or acquired heart disease are frequently encountered in Marfan patients. Fifteen percent of Marfan patients with aortic root dilatation presents an associated chest wall deformity such as pectus excavatum (PE) [1].

The concomitant presence of cardiac disease and pectus that both necessitate surgical intervention create a dilemma for surgeons and many questions remain controversial.

MOST OF CHEST WALL DEFORMITIES ARE PECTUS EXCAVATUM (PE)

Pectus excavatum is caused by disturbances in the growth of the sternum and costal arches. The involved cartilages can be fused, deformed or rotated. Intrinsic abnormality of the costochondral cartilages is suggested by occurrence among patients with connective tissue disorder.

PE is most frequently recognized during early childhood. During adolescent growth the severity of the depression increases until full skeletal maturity is achieved. Worsening of symptoms and cardio-pulmonary function can be observed with increasing ages. PE is more than a cosmetrical problem. The severity of defect is not correlated to the severity of symptoms.

Surgery can be considered in patients close to the age of skeletal maturity, younger patients with cardiopulmonary compromise may also be candidates for repair but a too early repair can lead to improper growth of the chest wall or recurrences.

Criteria for surgical referral are listed as below (table 1)

Table 1. Criterias for surgical referral

Criteria for surgical referral (At least 2)
-Symptomatic
-Aggravation of deformation
-Paradoxal movement of chest wall
-Haller > 3,0
-Cardiac compression
-Pulmonary compression
-Restrictive syndrome
-Mitral valve prolapsus
-Cardio-pulmonary dysfunction in exertion (VO_2 /Heart Rate)
-Dysmorphism
-Failed reparation

OPERATIVE TECHNIQUES FOR PECTUS EXCAVATUM

The first breakthrough in management came in 1949 when Ravitch described costochondral osteotomy to repair PE. Robicsek made modifications to this procedure using sternal turnover and stabilizing mesh.

In 1998 Nuss introduced a minimally invasive repair by temporarily implanting metal bars.

Johnson et al. conducted a systematic review to help physicians to choose between Nuss and Ravitch in adult and pediatric patients [2]. In adult group 262 Nuss procedure patients were compared to 498 highly modified Ravitch procedure patients. The outcome were similar 91% of good or excellent in Ravitch versus 88% in Nuss. Difference were observed in operation time (191 min vs 94 min). Non displacement complication rate for Ravitch (8%) was much lower than Nuss (21%) suggesting a tendency for fewer relevant complications with the Ravitch procedure. Nuss in adults has greater tendency for bar displacements, the use of stabilizers, suture fixation, stronger bar and placement technique must be studied. Nuss was traditionally reserved to children but Park et al. [3] shown that adult patients can also have benefit from Nuss procedure.

In pediatric groups 1500 Nuss procedure patients were compared to 1186 modified Ravitch procedure patients. Outcomes were similar 96% of good or excellent result in Ravitch versus 95% in Nuss.

Pediatric patients will have greater potential benefit from the Nuss procedure rather than the Ravitch Procedure.

In conclusion Nuss and Ravitch are viable at all ages.

The involvement of the aortic root is correlated to prognosis in Marfan patients. In such situations a prophylactic replacement of the aortic root is indicated. This intervention should be realized ideally in any condition of acute aortic syndrome.

Historically the replacement was performed by a Bentall technique. The aortic root and valve were replaced. In young patients a mechanical prosthetic valve was usually chosen. The use of life oral anticoagulation is responsible of morbidity because of thrombotic or hemorrhagic event. Prosthetic valves are more susceptible for endocarditis than native valves.

Sometimes the mechanism of aortic leak does not involve the valvular tissue and is the consequence of ectasia of the aorta. The most used technique nowadays is the Tirone David technique that is also known as the inclusion technique.

The Tirone David procedure has excellent long-term outcomes and has become an increasingly popular alternative to aortic root replacement especially in young Marfan patient to avoid lifelong anticoagulation [4].

When there is both surgical indications for chest wall deformity and heart disease, the surgeon can choose between 2 main strategies: combined repair or staged repair.

The expected advantages of a staged repair are: less bleeding, infection and surgery time and less desvascularization of the sternum and cartilages [5,6].

Cardiopulmonary function may be compromised in chest wall deformities because of compression of right chambers, reduced ventricular filling [7] and reduced cardiac output during exercise [8]. Combined procedures can improve hemodynamic after surgery but is associated with higher pain [9]. In one case an emergent PE repair was conducted immediately after sternal closure because of serious hemodynamic compromise. Cardiac compression is known to result in postoperative hemodynamic instability and impairment of pulmonary function jeopardizing a successful outcome [10].

There is actually no consensus, historically staged approaches were conducted but sporadic cases of simultaneous repair were reported with great results [11-13] (Table 2).

Table 2. Summary of cases and series of simultaneous repair

METHODS

A retrospective review was conducted of patients who underwent chest deformity repair and cardiac surgery at the same time from January 2007 to May 2014. All datas were collected prospectively in our data base.

We collected demographic, operative and post operative datas.

The evaluation of satisfaction was defined in excellent if the chest wall aspect was normal, good if a minimal deformation was still visible or failed in case of recurrence or fail in reparation.

All patients were approached by a mid-sternotomy. The cardiac intervention was performed under cardio-pulmonary bypass (CPB). CPB was conducted at 32 °C. Anterograde cardioplegia was induced by a cold cristalloid solution (St Thomas).

At the end of procedure, patients were warmed to 37°C. CPB was weaned, canulas were retired. Antagonisation of heparin was performed. The chest drainage was put in place after completion of hemostasis of the operative field.

After sternal closure modified Ravitch or Nuss procedure was performed.

For the Ravitch technique the chondral cartilages was largely dissected. Chondrotomies and osteotomies was performed step by step to ensure a good mobilization of the sternum. The reconstruction was secured by metal bares (Strasbourg Thorax Osteosyntheses System—STRATOS™, MedXpert GmbH, Heitersheim, Germany).

A review of English literature was conducted to collect all published cases of combined aortic valve sparing root replacement and correction of a pectus excavatum.

RESULTS

Patient demographics and comorbidities (Table 3).

In our serie 11 patients underwent a concomitant repair of heart disease and pectus.

Mean age was 27.3 ± 17 years and the sex ratio M/F was 8/3.

Ten patients were Marfan patients. Six patients followed for aortic root aneurysm underwent an aortic valve sparing root replacement (Tirone David procedure), 5 patients underwent a mitral valve repair and 1 patient a mitral valve replacement.

3 patients underwent pectus carinatum repair (modified Ravitch) and 8 patients underwent a PE repair (6 Nuss procedure, 2 modified Ravitch procedure). One patient underwent a concomitant Tirone David, mitral valve repair and modified Ravitch procedure for pectus carinatum.

Table 3. Patients demographics. The last 4 patients below the line are patients who underwent pectus excavatum repair and aortic valve sparing root replacement

Age	Sexe	Deformation	Aortic diameter	Cardiac intervention	Chest wall reparation	CPB time	Aortic clamp time	Blood loss	Complications	Satisfaction
17	M	PC	52	Tirone David	Ravitch	190	177	330	-	Excellent
25	M	PC	51	Tirone David + MVP	Ravitch	236	208	550	Atrio-ventricular block, superficial wound infection	Excellent
63	M	PE	-	MVP	Nuss	96	68	480	-	Excellent
52	F	PC	-	MVP	Ravitch	89	58	430	-	Excellent
27	F	PE	-	MVP	Nuss	85	49	380	-	Excellent
24	M	PE	-	MVP	Nuss	104	78	560	Chronic pain	Good
8	M	PE	-	MVR	Ravitch	83	56	220	-	Good
21	M	PE	54	Tirone David	Nuss	144	127	410	-	Excellent
19	M	PE	51	Tirone David	Nuss	215	202	2100	Superficial wound infection, transfusion	Good
19	F	PE	48	Tirone David	Ravitch	210	196	890	Transfusion	Good
17	M	PE	47	Tirone David	Nuss	195	165	670	Transfusion	Excellent

A total of 4 patients underwent an aortic valve sparing root replacement and correction of PE (3 Nuss procedure and 1 modified Ravitch procedure). All patients were white and 3 were male. All of these 4 patients were Marfan patients. Mean age was 19 ± 1.63 years and mean aortic diameter was 50 mm (range 47-54).

All patients reported 2 or more symptoms, all patients complained of exertional dyspnea, 3 of exercise intolerance. One patient presented upper respiratory infection.

In the post operative course, blood loss was 1017.5 mL (range 410-2100mL).

Results were good for 2 patients and excellent for 2 patients. One patient had superficial wound infection requiring oral antibiotherapy. 3 patients required transfusion in our serie. None patient required a revision for hemostasis.

Pain was controlled by Patient Controlled Analgesia (PCA). The mean length of stay was 14.5 days (11-21). No bar displacement was observed. One patient underwent removal of the material and at 1 year of follow-up, result was excellent.

DISCUSSION

Ideally pectus should be corrected before any cardiac intervention to diminish cardiac compression. In young Marfan patients a prophylactic replacement of the aortic root can be necessary in case of aortic ectasia or aneurysm because of high risk of rupture. The association of aortic valve sparing root replacement and correction of pectus excavatum represents a safe alternative to stage approaches.

Multiple approaches have been proposed for simultaneous repair of PE and cardiac disease [12]. The presence of PE is a technical challenge in cardiac surgery since the sternum is rotated and the heart posteriorly displaced. Alternatives to midsternotomy in these conditions include lateral thoracotomy or turnover techniques [14,15]. However only midline approach insure adequate exposure of the aortic root [13,16].

Concomitant repairs have been reported and are resumed in table 2.

Casamassima [16] reported 7 patients (M/F = 6/1) who underwent concomitant PE repair by Nuss procedure and aortic valve sparing root replacement for aortic aneurysms.

Kawamura [17] reported the case of a 32 year-old female who had PE and annulo-aortic ectasia treated successfully by modified Ravitch and aortic valve sparing root replacement.

Including our series (4 patients), 12 patients successfully underwent this strategy.

Sex ratio M/F is 9/3. In 10 patients PE was treated using a Nuss procedure, modified Ravitch in the last 2 patients.

Outcomes were excellent and no patient required revision for hemostasis. In our series 2 patients needed transfusion for postoperative bleeding through chest tubes without impairing clinical results.

Bleeding is a potential complication in combined procedures after cardiopulmonary bypass. By avoiding the need for early anticoagulation, the Tirone David repair is an interesting strategy for patients sharing aortic root aneurysm and chest wall deformity. Controversy however persists considering the choice between the Ravitch and the Nuss techniques for PE correction [18,19]. Cartilage resection associated with muscular flap detachment in the Ravitch technique may present a greater risk of major bleeding for patients requiring immediate anticoagulation therapy after aortic root surgery. When the aortic valve can be preserved, Tirone David procedure is preferred compared to Bentall. Preservation of the native valve avoids the need for anticoagulation therapy and is thus a more adapted approach for combined correction of chest wall deformities. Moreover surgeons remain divided considering the use of retrosternal devices, which may dramatically impair cardiopulmonary resuscitation in case of early postoperative tamponade and circulatory arrest. Picton elaborated recommendations for resuscitation after Nuss procedure including anteroposterior placement of defibrillation paddles, exclusion of tension pneumothorax, monitoring of capnography or invasive blood pressure monitoring [20]. We add to these recommendations a second sterilized handles set to be kept to quickly remove the bar and replace it after resternotomy for major postoperative bleeding.

Our approach for the concomitant repair of aortic root dilatation and PE using respectively Tirone David and Nuss procedures is safe and effective with no apparent detriments. It achieved excellent functional and cosmetic results. Valve sparing procedures combined with mini-invasive correction of chest wall deformity may represent an interesting one-stage surgical approach in Marfan patients if validated by larger case series.

CONCLUSION

A single stage repair of both chest wall deformity and heart disease is safe and feasible in Marfan patients suffering of PE and aortic aneurysm.

The aortic valve sparing root replacement (Tirone David technique) by avoiding anticoagulation can be very interesting in such patients.

The choice of Nuss or modified Ravitch procedure remains unclear. In this small serie both strategies were safe with good or excellent results.

Chapter 52

SEVERE PERIODONTITIS IN MARFAN SYNDROME

Naoto Suda

Division of Orthodontics, Department of Human Development and Fostering
Meikai University School of Dentistry, Sakado-shi, Saitama, Japan

ABSTRACT

Marfan syndrome frequently causes cardiac complications such as, aneurysm and dilatation of the aortic root. Many Marfan syndrome patients have these cardiovascular problems, and the surgical replacement of aortic and mitral valve, and aortic roots is frequently required. In addition, cases are associated with severe periodontitis, which is a chronic inflammation of the gingiva, periodontal ligament, and alveolar bone. Because of the surgical replacement, it is essential to prevent dental infection, such as infectious endocarditis caused by the periodontitis. In Marfan syndrome, an unfavorable oral hygiene due to the crowded teeth and narrow dental arch had been thought as a cause of severe periodontitis. However, clinical and basic studies have highlighted the genetic background as a pathogenesis of the severe periodontitis. It is suggested that cell alignment and tissue architecture of periodontal ligament are impaired in the model mice of Marfan syndrome. The model mice were more susceptible to alveolar bone resorption after the infection of *Porphyromonas gingivalis*, which is known to cause chronic periodontitis. It is likely that activated TGF- β signaling upregulates IL-17 and TNF- α levels, resulted in the increased alveolar bone resorption. In this review, the perspective of the dental management and the effect of angiotensin II receptor blocker are discussed.

1. CARDIAC PROBLEMS AND ANGIOTENSIN II RECEPTOR BLOCKER (ARB) IN MARFAN SYNDROME

Marfan syndrome is an autosomal dominant connective tissue disease that affects about one in 5,000 individuals [1]. The responsible gene of this syndrome is *FBN1* which encodes the extracellular matrix protein fibrillin-1 [1]. *FBN1* mutations lead to defects in multiple organs including skeletal, cardiovascular, and ocular systems [2]. Among them, the most serious problems are seen in the cardiovascular system, such as, aortic regurgitation, aneurysm

and dissection of the aortic root, mitral valve prolapse, and mitral regurgitation, causing a short life expectancy in patients [3].

It is reported that fibrillin-1 regulates the function of endogenous transforming growth factor (TGF)- β by targeting the respective complexes to the extracellular cell matrix [4]. Studies of animal [5] and human [6] reported that TGF- β signaling drives aneurysm progression in the aorta [7]. Since Marfan syndrome patients have cardiovascular problems, the surgical replacement of aortic and mitral valve, and aortic roots is often required [3].

It is known that effects of angiotensin II are mediated by two receptors, the AT1 receptor (AT1) and the angiotensin II type 2 (AT2) receptor [8]. AT1-receptor signaling can increase the production of TGF- β ligands and receptors [9]. Angiotensin II-receptor blockers (ARBs) selectively blocking the angiotensin II binding to its receptor within the renin-angiotensin system [10]. AT1-receptor blockade decrease the TGF- β signaling, resulting in the inhibition of phosphorylation of Smad2. Recently, losartan, one of the angiotensin II-receptor blockers (ARBs) have been reported to suppress the progression of aortic root dilation by inhibiting TGF- β signaling [5, 11]. Application of ARBs are now providing great benefit to Marfan syndrome patients by improving cardiovascular conditions.

2. PERIODONTAL DISEASE IN MARFAN SYNDROME

Oral manifestations are not included as diagnostic criteria of Marfan syndrome, but it is reported that this disease is frequently affected with severe periodontitis [12-14].

Periodontitis is an inflammatory condition affecting periodontal tissues, including gingiva, periodontal ligament (PDL), and alveolar bone [15]. It is reported that approximately 15% of the adult population has an advanced form of periodontitis, causing multiple negative impacts on quality of life [16, 17]. Consequences of periodontitis include negative esthetics, and functional problems in occlusion, chewing and speaking, and finally result in tooth loss [18, 19].

Periodontitis is initiated by chronic inflammation and immune reactions to bacterial pathogens [20]. It is known that several bacteria play important roles in the pathogenesis of periodontitis, but *Porphyromonas gingivalis* playing a central role in pathogenesis of periodontitis [21].

It is reported that 87.5% of Marfan syndrome patients had periodontitis with more than 4 mm of periodontal pocket depth, while only 35.7% of healthy volunteers were with this condition [22]. Interestingly, higher percentage of periodontitis with more than 4 mm of periodontal pocket depth was seen in patients with cardiovascular disease than those without cardiovascular disease [23]. Also, there was lower percentage of remaining teeth in the former than in the latter. Many Marfan syndrome patients have these cardiovascular problems, and the surgical replacement of aortic and mitral valve, and aortic roots is often required [3]. Because of this surgical replacement, it is essential to prevent dental infection, such as infectious endocarditis caused by the periodontitis and caries.

The reason of higher percentage of severe periodontitis in Marfan is not known. However, the lower number of caries has been reported in adult Marfan syndrome patients than in healthy volunteers [12]. This implies that periodontal tissues but not teeth have structural problems causing susceptible to severe periodontitis. The abnormal alignment of collagen fibers were

observed in one of the model mice of Marfan syndrome (MgR mice). Homozygous MgR mice show that 72% of reduction in *Fbn1* (encoding mouse fibrillin-1) expression as a result of transcriptional interference by insertion of the PGK*neo*-cassette [24], and resemble the phenotype of Marfan syndrome by showing 10% longer long bones than wild-type littermates. A comparable level of type I collagen, which is the most major collagen in periodontal ligaments, was expressed in PDL-cells of homozygous MgR mice as in wild type mice [25]. However, multi-oriented collagen fiber bundles with a thinner appearance were noted in homozygous mice, whereas well-organized definite collagen fiber bundles were seen in WT mice. This suggests that normal level of fibrillin-1 is indispensable for the normal architecture of periodontal ligament.

3. ARB AND PERIODONTAL DISEASE

Telmisartan is an ARB used in the management of hypertension [26, 27] and expected as an effective drug for the management of vascular condition in Marfan syndrome [28]. This drug has a binding affinity 3,000 times higher for AT1 than receptor type 2 (AT2) [29]. Telmisartan, was examined in a mouse model of Marfan syndrome (Mg Δ). Heterozygous Mg Δ mice, another mice model of Marfan syndrome, show half level of *Fbn1* as WT mice [24]. Six-week-old male heterozygous Mg Δ and WT mice were challenged with *Porphyromonas gingivalis* with and without telmisartan application [30]. Infection of *Porphyromonas gingivalis* induced alveolar bone resorption in both heterozygous Mg Δ and wild-type mice. The amount of alveolar bone resorption was significantly larger in the former than the latter (Figure 1A).

Interleukin (IL)-17 and tumor necrosis factor (TNF)- α levels were significantly higher in infected Mg Δ mice than infected wild-type mice. Telmisartan treatment significantly suppressed the alveolar bone resorption of infected Mg mice (Figure 1A). Telmisartan also significantly decreased levels of TGF- β IL-17 and TNF- α in infected Mg Δ mice to levels seen in infected wild-type mice (Figure 1B and C). This study suggests that ARB can prevent the severe periodontitis frequently seen in Marfan syndrome.

PREIMPLANTATION GENETIC DIAGNOSIS FOR MARFAN SYNDROME

Anver Kuliev* and Svetlana Rechitsky

Reproductive Genetics Innovations, Northbrook, IL, US

INTRODUCTION

Preimplantation genetic diagnosis (PGD) was introduced 24 years ago with the purpose of performing genetic testing before pregnancy, in order to establish only unaffected pregnancies and avoid the need for pregnancy termination, which is the major limitation of traditional prenatal diagnosis [1-2]. Despite the requirement for ovarian hyperstimulation and in vitro fertilization (IVF), needed to perform genetic testing of oocyte or embryo prior to transfer, PGD has been accepted in most parts of the world [3-5]. Thousands of PGD cycles have now been performed for single gene disorders, with PGD presently offered for some indications that have never been practiced in prenatal diagnosis, such as late onset diseases with genetic predisposition, and preimplantation HLA typing [6-9]. The present paper describes our experience on PGD for Marfan syndrome, caused by *FBN1* gene, which was performed in 38 cases, as part of our PGD experience of 2,860 cycles for single gene disorders, which is the world's largest PGD experience.

Similar to other autosomal dominant conditions, Marfan syndrome is important candidate for PGD, as couples have a 50% risk of producing an affected child.

Our experience of PGD for Marfan syndrome is presented in Table 1, summarizing the data of 38 PGD cycles performed for 20 couples at risk for producing offspring with Marfan syndrome. PGD was performed either by polar body testing, in cases of maternally derived mutations, or by embryo biopsy, involving blastomere or blastocyst biopsy [10-11]. Overall, 410 oocytes or embryos were biopsied, including 107 oocytes tested by polar bodies sampling, following oocytes maturation and fertilization, and 303 embryos tested by blastomere biopsy in 239 cases, and blastocyst biopsy in 64. Of 310 embryos with conclusive results, 158 (51%) were mutant, and 152 (49%) free of *FBN1* mutation, of which 59 were pre-selected for transfer

in 30 cycles (1.9 embryos on the average), resulting in 16 (53%) clinical pregnancies and birth of 14 healthy children, confirmed to be free of Marfan syndrome.

Table 1. Preimplantation Genetic Diagnosis for Marfan Syndrome

Test Type	Patients	Cycle	ET***	#Embryos Transferred	Pregnancy	SAB#	Birth/Baby	Families with De Novo Mutations
MARFAN	9	21	20	45	11(55%)	4(25%)	7/9	7
MARFAN+A* (PCR)	6	11	9	13	4	0	4	3
MARFAN+24A**	5	6	1	1	1	0	1	1
SUBTOTAL	11	17	10	14 (1.4)	5 (50%)	0	5/5	4
TOTAL	20	38	30	59 (1.9)	16 (53.3%)	4 (25%)	12/14	11

*Aneuploidy Testing.

**24-Chromosome Aneuploidy Testing.

*** Embryo Transfer #Spontaneous abortions.

Because a half of the PGD couples were of advance reproductive age, concomitant aneuploidy testing was performed in 17 of 38 cycles, including 24-chromosome aneuploidy testing in 6 of them. It is of note that 4 of 16 pregnancies resulting in spontaneous abortions were from those cycles performed without aneuploidy testing.

It is also of interest that 11 of 20 PGD couples were with *de novo* mutations, and presented a particular challenge, as the family members were free of *FBN1* mutation to be able to establish the relevant haplotypes, required for performing PGD with sufficient level of accuracy.

Of these 11 couples, 4 were with paternally derived mutation, so we performed single sperm typing to establish the relevant haplotypes, while 7 were with maternally derived mutation, in which the polar body testing was method of choice. Irrespective of mutation origin, no misdiagnosis was observed, with confirmation of mutant gene in affected embryos avoided from transfer, and the mutation free status in all 14 children born as a result of PGD.

The presented data demonstrate the utility of PGD for Marfan syndrome, suggesting that the at risk couples should be informed about the availability of the PGD technology, which may be applied irrespective of mutation origin and also combined with aneuploidy testing to improve the outcome of PGD in at risk couples with advance reproductive age.

ABSTRACT

The order Anura currently encompasses over 6,800 amphibian species distributed in 56 families and is an interesting group for cytogenetic studies. Whereas some groups of species present conservative karyotypes, others are highly variable in diploid number or number/location of diverse chromosomal markers, such as nucleolus organizer regions, heterochromatic bands and specific satellite DNA sites. In some cases, karyotypic variation overcomes morphological diversification, turning cytogenetics into a useful tool for taxonomy. Special variation is observed with respect to sex chromosomes and sex determination systems, with both female and male heterogameties observed. Although most species already karyotyped do not show sex chromosome heteromorphism, distinct levels of differentiation are observed between the sex chromosomes of several species, which makes this group particularly interesting for studies of sex chromosome evolution. In this chapter, we explore the use of cytogenetic data for studies of frogs as well as the insights that hypotheses of phylogenetic relationships have added to this issue. In addition, we provide a brief review of PcP190 satellite DNA (with new data for the genus *Engystomops*), sex chromosome systems and B chromosomes found in Anura.

1. CYTOGENETICS, TAXONOMY AND PHYLOGENETIC INFERENCES

In the last 15 years, knowledge of frog taxonomy and systematics has increased dramatically, boosted by the inclusion of DNA sequences in analyses. Phylogenetic relationships at the family level (Frost et al., 2006; Grant et al., 2006; Pyron & Wiens, 2011; Padial et al., 2014; Duellman et al., 2016; Feng et al., 2017) and especially in lower taxonomic levels (examples in Faivovich et al., 2012; Blotto et al., 2013; De Sá et al., 2014; Vacher et al., 2017; Chen et al., 2017) have been inferred, motivating several taxonomic revisions. The number of amphibian species descriptions has risen rapidly (Kohler et al., 2005), with over 100 species of frog described between January and November 2017 (based on to the list provided by Frost, 2017), but the species-level diversity of amphibians remains underestimated (see analysis provided by Giam et al., 2012; for examples of recent disclosure of still unnamed species, see Funk et al., 2012; Caminer et al., 2017; Chen et al., 2017, among others). In parallel, several species have been synonymized (examples in Guarnizo et al., 2012; Orrico et al., 2013, 2017).

In this scenario of frequent taxonomic changes and uncertainties, particular attention should be devoted to the identification of cytogenetic data available for frogs. There are several examples in the literature of species with cytogenetic data described or discussed under different names, which brings additional complexity when assembling specific cytogenetic data. That is the case, for example, for the craugastorid species currently known as *Strabomantis biporcatus*, whose karyotype was first described as belonging to *Eleutherodactylus maussi* (Schmid et al., 1992, 2002a), or the dendrobatid *Ranitomeya vanzolinii*, whose karyotype was first described by Bogart (1991) and assigned to *Dendrobates quinquevittatus* (a synonym junior of *Ameerega quinquevittatus*) (see comments in Grant et al., 2006 and Rodrigues et al., 2011). Taking into account the recent improvement in DNA barcoding of frogs (Vences et al., 2005a,b; Fouquet et al., 2007; Lyra et al., 2016), an approach that has become useful to minimize taxonomic problems is to obtain DNA sequences from the same individuals analyzed cytogenetically (Targueta et al., 2010; Medeiros et al., 2013; Veiga-Menoncello et al., 2014; Teixeira et al., 2016).

The increasing number of phylogenetic studies of frogs has also improved inferences of karyotypic evolution. The evolutionary comparison of karyotypes involves the inference of interspecific chromosomal homeologies and changes, which relies on the identification of many chromosomal markers. Therefore, the greater the number of chromosomal markers available for a representative sample of the taxonomic group of interest and its outgroup, the better the chances of obtaining informative data for the inference of karyotypical evolution. However, the chromosomal markers usually obtained in cytogenetic studies of frogs are scarce, with most of them being restricted to diploid number, chromosomal morphology (i.e., chromosome size and centromeric position), and location of heterochromatin and nucleolus organizer regions (NORs). Although some important phylogenetic groups were first recognized based on their diploid numbers, as the 30-chromosome hylids (currently the *Dendropsophus* genus – see Faivovich et al., 2005) and the *Sclerophrys regularis* group (known as the 20-chromosome toads – see Cunningham & Cherry, 2004 and references therein), the available chromosome markers have usually been insufficient for the proposition of substantial chromosomal evolutionary hypotheses. Accordingly, proper karyotypic evolutionary inferences have been facilitated by the tracking of chromosomal characters in cladograms inferred from other source

of data, mostly DNA sequence matrices (examples in Lourenço et al., 2008, 2015; Cardozo et al., 2016). This approach involves the optimization of chromosomal characters based on the parsimony criterion, and has allowed for the recognition of a number of putative chromosomal synapomorphies as well as homoplastic characters, either concerning diploid chromosome number, chromosome morphology, NOR location or heterochromatic bands, as exemplified below.

1.1. Inferences of Evolutionary Changes in Diploid Number

Diploid chromosome number is easily coded as a phenotypic character and can be readily included in data matrices used for phylogenetic inferences (see example in Grant et al., 2006). The amount of missing data regarding diploid number of frogs, however, is still extensive, and most available inferences of transformations related to this character have derived from its analysis in the light of phylogenetic hypotheses inferred previously or from other sources of data. Some examples of chromosome number transformations already inferred for anurans are listed here.

- (i) Progressive reduction in diploid number from 2n = 22 to 2n = 20, 18 and 16 in the leptodactylid genus *Pseudopaludicola* (Veiga-Menoncello et al., 2014; Cardozo et al., 2016), with a parallel origin of a 20-chromosome karyotype in *Pseudopaludicola boliviana* (Cardozo et al., 2016).
- (ii) Increase in chromosome number from 2n = 24 to 2n = 30 as a synapomorphy of the hylid genus *Dendropsophus* (Suárez et al., 2013; Faivovich et al., 2005).
- (iii) Three independent changes in diploid number from the plesiomorphic 2n = 26 to 2n = 30, 2n = 34, and 2n = 22 in the alsodid genus *Alsodes* (Blotto et al., 2013).
- (iv) Reduction from 2n = 24 to 2n = 22 due to a putative fusion of chromosomes 3 and 12 as a synapomorphy of the *Aplastodiscus albofrenatus* group (Hylidae), and independent change of the plesiomorphic condition 2n = 24 in the *Aplastodiscus albosignatus* group (sensu Berneck et al., 2016) (Gruber et al., 2012a; Berneck et al., 2016). Berneck et al. (2016) note that changes in diploid number in the *A. albosignatus* group are still ambiguous as the karyotypes of most species of this group are still unknown but consider the hypothesis of a former reduction to 2n = 20 and a sequential reduction to 2n = 18 in this group (as previously proposed by Gruber et al., 2012a).
- (v) Reduction from 2n = 22 to 2n = 20 as a synapomorphy of the Duovox clade of the leptodactylid genus *Engystomops* (Targueta et al., 2012).
- (vi) Reduction from 2n = 22 to 2n = 20 as a synapomorphy of the *Sclerophrys regularis* group (Bufonidae), with a reversion to 2n = 22 in *Sclerophrys pardalis*, was inferred in the phylogenetic study conducted by Cunningham & Cherry (2004). The authors, however, emphasize the need of further analysis to verify this hypothesis of reversion as they could not statistically discard the alternative arrangement of *S. pardalis* as the sister species of the group composed of the 20-chromosome toads.
- (vii) Increase from 2n = 24 to 2n = 28 in the hylid species *Pseudis cardosoi* as a result of two centric fission events (Busin et al., 2001; Aguiar-Jr. et al., 2007).
- (viii) Reduction from 2n = 24 to 2n = 22 in the hylids *Phyllodytes edelmi* and *Phyllodytes luteolus* (Gruber et al., 2012b). Because the interspecific relationships in *Phyllodytes*

remain unknown as well as the diploid number of other species of this genus, it is not possible to evaluate if the diploid numbers of *P. edelmoi* and *P. luteolus* have resulted from the same evolutionary event or if this condition is shared with other *Phyllodytes* species. However, the reduction in diploid number could be inferred considering that $2n = 24$ is a putative synapomorphy of the subfamily Hyliinae, as suggested by Faivovich et al. (2005) (Gruber et al., 2012b). Also based on this assumption, Gruber et al. (2007) inferred the reduction from $2n = 24$ to $2n = 22$ in the hylid species *Boana albopunctata*.

Although some rearrangements and chromosomes have been considered as possibly involved in some of the aforementioned cases (see discussions in Gruber et al., 2007, 2012a,b; Cardozo et al., 2016), only the diploid reduction observed in *Pseudis cardosoi* could be associated with an explicit proposal of chromosome rearrangements (Busin et al., 2001). In this case, based on chromosome morphology, C-bands and NOR site, Busin et al. (2001) inferred a reliable hypothesis of homeology between the chromosomes of *P. cardosoi* and its sister species *P. minuta* (see Aguiar-Jr. et al., 2007), according to which the bi-armed chromosomes 1 and 4 of *P. minuta* would be homeologous, respectively, to the telocentric chromosomes 6 and 7 and chromosomes 8 and 9 of *P. cardosoi*. Based on this hypothesis of homeology, and considering $2n = 24$ as the plesiomorphic state for the group in analysis, Busin et al. (2001) suggested that chromosomes 6, 7, 8 and 9 of *P. cardosoi* have arisen from centric fissions of the same ancestral chromosomes that have led to chromosomes 1 and 4 of *P. minuta*.

Phylogenetic inferences have also assisted the analysis of changes in chromosome number that are derived from polyploidization. In the study of the diploid *Dryophytes chrysoscelis* and the tetraploid *Dryophytes versicolor* (as *Hyla versicolor*), the phylogenetic analyses supported the hypothesis that *D. versicolor* is possibly polyphyletic, as tetraploids were inferred to have arisen multiple times in this group (Ptacek et al., 1994; Holloway et al., 2006). Another interesting example is found in the genus *Xenopus*, in which independent and recurrent polyploidization events have been inferred (Evans et al. 2004, Evans, 2007, 2008).

1.2. Inferences Related to Chromosomal Morphology or Chromosomal Markers

In contrast to coding of diploid chromosome number, coding of other chromosome characters (such as chromosome morphology, chromosome markers or even chromosome rearrangements) is more complex and depends on reliable hypotheses of interspecific chromosome homeology. Usually, the description of frog karyotypes does not provide detailed characterizations of each chromosome, as the available information is typically limited to size, centromeric position (which allows chromosome classification as metacentric, submetacentric, subtelocentric, and telocentric, following the criteria proposed by Green & Sessions, 1991), and presence of C-bands and NORs. The paucity of informative markers prevents proper comparisons among karyotypes and as a result many karyotypes were described without any discussion of primary hypotheses of interspecific chromosome homeology, with chromosomes arranged by size and numbered in decreasing order. In addition, as different chromosomes of the same karyotype may present similar lengths and centromeric positions, this criterion of chromosome classification and karyogram organization has proved to be ineffective as it may

cause errors in chromosome numbering, which adds further problems for the comparison of described karyotypes.

Measurement of chromosomes using specific software (as MicroMeasure – Reeves & Tear, 2000; IdeoKar – Mirzaghaderi & Marzangi, 2015; KaryoType – Altinordu et al., 2016; Drawid – Kirov et al., 2017) may help minimize huge discrepancies in karyotype descriptions, but it does not eliminate the problem. Taking measurement of centromeric regions or curved chromosome arms may be complicated and may vary from one research study to another. In addition, chromosome compaction degree varies amongst different metaphase cells, even in the same individual, and sometimes even between the homologues in a single cell, which may interfere in the calculation of chromosome relative length (RL) and arm ratio (AR) or centromeric index (CI). Special attention should be given to borderline values when ordering the chromosomes by size or when classifying the chromosomes with respect to their centromeric positions. The selection of good-quality metaphases, avoiding supercompacted, curved or crossed chromosomes, is of fundamental importance when measuring chromosomes and could minimize some measurement problems. Nevertheless, chromosome measurements are not accurate enough to allow for the usage of RL, AR and CI as powerful parameters for karyotypic comparisons. Although important, these parameters should not be the only or the first criterion for assessing chromosome pairing or organizing karyograms. It is not rare that the best hypothesis of arrangement of Giemsa-stained chromosome pairs in a karyogram proves to be wrong after the same chromosomes are C-banded or silver stained.

The sequential analysis of the same chromosomes submitted to different techniques is therefore indicated as a powerful approach for a better characterization of each chromosome of a karyotype. Sometimes different chromosomes that are very similar in morphology bear distinct markers and, in these cases, if the techniques that enable the detection of these markers are not applied sequentially, a proper interpretation of the karyotype is precluded. This is the case, for instance, for chromosomes 3 and 4 of the leptodactylid *Physalaemus ephippifer*. These chromosomes are very similar in size and centromeric position and may be easily misidentified in Giemsa-stained metaphases, but they may be differentiated by the presence of a pericentromeric DAPI-positive C-band in the short arm of chromosome 3, which is also detected by 5S rDNA and PcP190 satellite DNA probes (Nascimento et al., 2010; Vittorazzi et al., 2014a).

Therefore, when assessing interspecific chromosome homeologies for further identification of shared characters, chromosome morphology may help, especially when all (or most) chromosomes are similar between the karyotypes in comparison, but the analysis of specific chromosome markers is indispensable. Using this approach, some reliable primary homeologies may be recognized even between chromosomes identified by different numbers according to their sizes and, especially in these cases, the homeology hypotheses should be explained (for examples, see discussion about the NOR-bearing chromosomes found in *Paratelmatobius* and *Scythrophrys*, and in species of the hyliid subfamily Scinaxinae – Lourenço et al., 2008 and Cardozo et al., 2011, respectively). In addition, when describing new karyotypes, it may be easier if the arrangement of chromosome pairs in karyograms reflects the homology hypotheses considered by the authors, even if the chromosome sizes suggest a distinct numbering. This type of decision was made when karyotypes of some species of *Physalaemus* were described (Tomatis et al., 2009; Vittorazzi et al., 2014b).

Once reliable chromosomal characters are recognized, interesting chromosomal synapomorphies, homoplasies, and evolutionary changes may be inferred. Some illustrative

cases are found in the hylid Scinaxinae, which is currently composed of the genera *Sphaenorhynchus*, *Oloolygon*, *Julianus*, and *Scinax* (Duellman et al., 2016), and in the leptodactylid genus *Physalaemus*. Cardozo et al. (2011), taking into account the phylogenetic relationships proposed by Faivovich (2002) and Faivovich et al. (2005), inferred the submetacentric morphology of chromosome pairs 1 and 2 and the NOR in chromosome pair 6 as three synapomorphies of *Oloolygon* (referred as *Scinax catharinae* clade in Cardozo et al., 2011). In addition, Cardozo et al. (2011) also recognized the NOR in chromosome pair 11 of *Oloolygon canastrensis* as a reversion to the plesiomorphic state of this character.

With respect to *Physalaemus*, by tracing cytogenetic characters in a cladogram inferred from DNA sequences, a telocentric chromosome pair 11 was inferred as a synapomorphy of the *Physalaemus signifer* clade, and this character was confirmed as homoplastic in relation to the telocentric chromosome 11 of *P. fernandezae* (Lourenço et al., 2015 and references therein), as formerly hypothesized by Tomatis et al. (2009). The phylogenetic relationships inferred for this genus also allowed for the recognition of a large C-band of the short arm of chromosome 3 as a synapomorphy of the clade composed of *Physalaemus biligonigerus*, *P. marmoratus* and *P. santafecinus*, and as a homoplasy in relation to the large C-band found in the short arm of chromosome 3 of *P. nattereri* (Lourenço et al., 2015 and references therein), as previously suspected (Vittorazzi et al., 2014b). Additionally, the interstitial C-band in the metacentric chromosome 5 was confirmed as a synapomorphy of the *P. cuvieri* species group (Lourenço et al., 2015 and references therein).

2. CYTOGENETICS AS A HELPFUL TAXONOMIC TOOL

Some groups of species present a high degree of karyotypic similarity. The bufonid species *Rhinella crucifer*, *R. icterica*, *R. jimi*, *R. rubescens*, and *R. schneideri* provide an evident example of this, as their karyotypes could not be distinguished by chromosome morphology or position of NOR and C-bands (Kasahara et al., 1996, as species of *Bufo*; Amaro-Ghilardi et al., 2008, as species of *Chaunus*). On the other hand, in some cases notorious interspecific differences are noted, and sometimes karyotypic variation overcomes morphological diversification, turning cytogenetics into a useful tool for taxonomy.

The finding of a new diploid number ($2n = 30$) in the genus *Alsodes*, for example, helped in the description of *Alsodes norae* (Cuevas, 2008). In the case of the hylid species *Dendropsophus nanus* and *D. sanborni*, which are very similar morphologically, cytogenetic analyses assisted in taxonomic identification, as their karyotypes could be easily distinguished by the number of telocentric chromosomes (the fundamental number is 52 in *D. nanus* and 50 in *D. sanborni* – Medeiros et al., 2003).

In some cases, conspicuous karyotypic divergences are observed between specimens assigned to a single species, supporting suspicions of the presence of distinct unnamed taxa. For instance, in the leptodactylid genus *Engystomops*, cytogenetic signatures were found for *E. freibergi* and *E. petersi*, and two additional karyotypes were described for specimens that belongs to distinct clades as inferred from DNA sequence analyses, which likely correspond to still unnamed species (Targueta et al., 2010; Funk et al., 2012).

The *Pseudopaludicola* genus gives other striking examples of interspecific karyotypic divergences, with the first reports of diploid number variation dating from the 1960s and 70s (see Veiga-Menoncello et al., 2014 for references). Despite this, for long time the cytogenetics

of *Pseudopaludicola* was underexplored. After obtaining well-characterized samples, some of them coming from topotype specimens, the diploid chromosome number could be confirmed for *P. falcipes* ($2n = 22$), *P. mineira* ($2n = 22$), *P. saltica* ($2n = 22$), *P. ameghini* ($2n = 20$), *P. ternetzi* ($2n = 20$), *P. canga* ($2n = 18$), and *P. mystacalis* ($2n = 16$), and some karyotypes had to be assigned to unnamed species (Duarte et al., 2010; Fávero et al., 2011). Three of these unnamed species were described latter as *P. facureae* (Andrade & Carvalho, 2012), *P. atragula* (Pansonato et al., 2014), and *P. motorzinho* (Pansonato et al., 2016). In addition, based on difference of chromosome number, *P. ameghini* was removed from synonymy with *P. mystacalis* (Fávero et al., 2011), which contributed for solving recurrent taxonomic conflicts. Based on how informative is the diploid number for *Pseudopaludicola*, the inclusion of karyotypic information in the description of new species may be helpful and has been adopted by some authors (see descriptions of *P. murundu* – Toledo et al., 2010; *P. jaredi* – Andrade et al., 2016; and *P. ibisoroca* – Pansonato et al., 2016).

3. HOW TO STUDY FROG CHROMOSOMES

Giemsa staining, C-banding, silver staining and *in situ* hybridization to reveal NORs, and, to a lesser extent, staining with base-specific fluorochromes (especially 4',6-diamidino-2-phenylindole – DAPI, chromomycin A3 – CMA3, and mythramycin – MM) are techniques commonly applied to the study of frog karyotypes. Unfortunately, informative markers are not easily obtained throughout euchromatic regions of anuran chromosomes, although very interesting data have been generated by replication banding using BrdU incorporation in some species (example in Schmid & Steinlein, 2015).

Given the importance of chromosomal markers for reliable interspecific karyotypic comparisons (as discussed in item 1.2), the prospect of new chromosome markers may be very helpful. In this context, besides the chromosome mapping of satellite DNA (as the PcP190 satellite DNA – see item 4), the production of chromosome probes from microdissected or flow-sorted material arises as an interesting strategy. Although chromosome painting has been frequently used for cytogenetic studies of several animals and plants (Hassanane et al., 1998; Shibata et al., 1999; Karamysheva et al., 2002; Marchal et al., 2004; Rubtsov et al., 2004; Diniz et al., 2008; Teruel et al., 2009a; Teruel et al., 2009b; Wang et al., 2009; Henning et al., 2011; Vicari et al., 2011; Kawagoshi et al., 2012; Silva et al., 2016; Pita et al., 2017; Romanenko et al., 2017), few studies have employed this technique for anuran cytogenetics (Krylov et al., 2010; Gruber et al., 2014; Uno et al., 2015; Targueta et al., in press).

Comparative gene mapping is another valuable strategy as it may identify syntenic blocks that are conserved in different species. Uno et al. (2013), for example, based on the chromosome mapping of 60 genes, recognized homeologous chromosome groups between *Xenopus tropicalis* and the allotetraploid species *Xenopus laevis* and inferred the occurrence of inter- and intrachromosomal rearrangements during the evolution of these frogs that could not be inferred by other approaches.

Finally, the comparative analysis of genomes has emerged as a powerful tool, as it allows for the identification of specific regions (sex specific, for example), which can be further mapped onto chromosomes. This promising approach has greatly improved the studies of sex chromosomes, as discussed in item 5 of this chapter.

4. PCP190 SATELLITE DNA

4.1. Satellite DNA as Chromosome Markers

Satellite DNA (satDNA) comprises tandemly repetitive sequences in genomes and is mostly located in centromeric and telomeric regions (Charlesworth et al., 1994; Elder & Tuner, 1995; Richard et al., 2008; López-Flores & Garrido-Ramos, 2012). These sequences can be present in large quantity in genomes, and several distinct families of satDNA can coexist in the same genome (Slamovits & Rossi, 2002; Plohl et al., 2008, 2012). An important feature of satDNA repeats is their non-independent (concerted) evolution, which may lead to a high level of sequence homogeneity among the repeats of a satDNA family (Dover, 1982, 1986; review by Plohl et al., 2008). Repeat homogeneity is achieved by mechanisms of non-reciprocal sequence transfer (such as unequal crossover, gene conversion, rolling circle replication and reinsertion, and transposition), and higher sequence similarity is expected among adjacent repeats than among repeats from different arrays of the same chromosome, repeats positioned on homologous chromosomes and repeats on non-homologous chromosomes, consecutively (Plohl et al., 2008, 2012). Additionally, the size of the repetitive blocks may vary greatly in the same genome and between organisms, even those related to functional centromeres (Warburton et al., 2000; Henikoff et al., 2001; Plohl et al., 2012).

Figure 1. Comparison between type I and II 5S rDNA and PcP190 satDNA. Type I and type II 5S rDNA coding regions are shown in red, and non-transcribed regions (NTS) are shown in blue. Type I and type II 5S rDNA differ mostly in length and composition of NTS. An alignment of type I and type II 5S rDNA and PcP190 sequences from *P. cuvieri* and *E. freibergi* is also shown. GenBank accession numbers of the sequences are shown. Annealing regions of primers frequently used to isolate 5S rDNA (5S-A and 5S-B primers – Pendas et al., 1994) and PcP190 sequences are indicated (P190F and P190R – Vittorazzi et al., 2011).

Among evolutionarily closely related species, it is possible that the same satellite DNA family has different numbers of repeats, distributions and compositions, since the evolutionary dynamics of these repetitive sequences favors amplification and continuous deletion in the genome of organisms, so new families arise continuously by restructuring older sequences (Meštrović et al., 1998; Ugarkovic & Plohl 2002; Plohl et al., 2008).

Figure 2. Alignment of all PcP190 sequences already described for anuran species. Only complete monomers are included, except for *Engystomops* and PcP-1b and PcP-6 sequences of *Pseudis tocantins*. The sequences are also identified by their GenBank accession numbers. Light gray boxes represent conservative sites and dark gray boxes are non-sequenced sites. Gaps are shown by white spaces and nucleotide polymorphisms, by colored boxes. Changes to thymine, cytosine, adenine, and guanine are represented by red, blue, green and black, respectively. Asterisks indicate the sequences obtained from microdissected chromosome 3 of *E. freibergi*. Note that these sequences are very similar to those obtained from *Physalaemus* species and to PcP-1a sequence of *Pseudis tocantins*.

Satellite DNA has been used as cytogenetic markers in comparative analysis of several organisms, such as insects, fish and mammals (Yamada et al., 2004; Saito et al., 2007; Acosta et al., 2007; Yoshimura et al., 2006; Cazaux et al., 2013; Matsubara et al., 2015; Ruiz-Ruano et al., 2016). The isolation and chromosome mapping of satellite DNA has also been employed in studies of some anurans (Table 1).

The satDNA PcP190 has proven to be widespread in frogs. It was first isolated from Leptodactylidae species (Vittorazzi et al., 2011) and has already been found in Hylodidae (Vittorazzi et al., 2014a) and Hylidae (Gatto et al., 2016) species to date. PcP190 satDNA is considered to be derived from 5S rDNA genes because of their high sequence similarity. Genetic similarities between the conserved region of Type I and II 5S rDNA and the corresponding regions in PcP190 were 70% and 66%, respectively, in *Physalaemus cuvieri* (Vittorazzi et al., 2011).

By comparing the nucleotide sequence of PcP190 fragments isolated from several frog species, two distinct regions can be recognized in the PcP190 repeats, one of which is more conserved, corresponding to the transcribing region of the 5S rDNA and one hypervariable region (Vittorazzi et al., 2014a, 2016; Gatto et al., 2016) (Figure 1). The hypervariable region varies both in size and nucleotide sequence and allows for the recognition of several different groups of sequences, including one group that is characterized by the absence of the hypervariable region (Gatto et al., 2016) (Figure 2).

While only one type of PcP190 sequence (Figure 2) was observed among the PcP190 fragments isolated from several species of *Physalaemus*, a great diversity of this satDNA was found in the hylid *Pseudis tocantins* (PcP-1 to PcP-7 sequence groups) (Figure 2; Table 1 and references therein). Different types of sequences were found adjacent to one another in the *P. tocantins* genome, supporting the occurrence of rearrangements between the distinct groups, although the homogenization process was less effective in this genome than in the *Physalaemus* genomes (Gatto et al., 2016). Based on the similarity between the coding region of 5S rDNA and the more conserved region of PcP190, and considering the great diversity among the non-transcribed regions of 5S rDNA, Gatto et al. (2016) discuss the possibility that the different groups of PcP190 sequences may have arisen from illegitimate recombination events between PcP190 satDNA and variants of the 5S rDNA. It should also be considered that the lower sequence variation in a specific region of the PcP190 satDNA repeats could be explained by differential selective pressures (Vittorazzi et al., 2014a; Gatto et al., 2016). In this context, it is worth noting that the same type of PcP190 sequences found in the *Physalaemus* species was observed in the *Pseudis* species as well (Figure 2; Gatto et al., 2016).

Clusters of PcP190 satDNA have been located at the centromeric/pericentromeric regions of some autosome pairs in seven *Physalaemus* species (*P. albifrons*, *P. albonotatus*, *P. centralis*, *P. cicada*, *P. cuvieri*, *P. ephippifer*, and *P. kroyeri*), raising the hypothesis that this satDNA could be involved in centromere biology in the studied species (Vittorazzi et al., 2014a, 2016); however, this has not been tested to date. In *Pseudis tocantins*, PcP190 satDNA was mapped exclusively to the large heterochromatic band in the long arm of the W chromosome, suggesting that this satDNA may have played an important role in the evolutionary differentiation of the sex chromosomes in this case. A differential distribution of PcP190 sequences was also observed between the sex chromosomes Z and W of *P. ephippifer*, although in this species chromosome 3 also bears a PcP190 site (Vittorazzi et al., 2014a).

4.2. PcP190 satDNA in *Engystomops*: Sequences and Chromosome Locations

The Neotropical genus *Engystomops* encompasses two clades, Edentulus and Duovox, which comprise the species located in the east and west side of the Andean Mountain range, respectively (Ron et al., 2006; 2010). The Edentulus clade is composed of *Engystomops freibergi*, *E. petersi*, *E. pustulosus* and two Confirmed Candidate Species not yet formally described, *E. "magnus"* and *E. "selva"* (Funk et al., 2012; Trillo et al., 2017). The Duovox clade includes *E. randi*, *E. montubio*, *E. guayago*, *E. coloradum*, *E. pustulatus*, and *E. puyango*. A diploid number reduction from $2n = 22$ to $2n = 20$ was considered as a synapomorphy of the Duovox clade, although the chromosome rearrangements involved in this event are not known (Targueta et al., 2012).

PcP190 satDNA is present in the genus *Engystomops* and PcP190 sequences could be isolated from the genome and from microdissected chromosome 3 of *Engystomops freibergi* (Figure 2). When compared to the conserved regions of the PcP190 sequences found in the leptodactylids *Physalaemus*, *Leptodactylus latrans*, *Crossodactylus gaudichaudii*, and the hylid *Pseudis tocantins*, the conserved region of the complete PcP190 monomers of *E. freibergi* showed from 83% to 88% of similarity (Table 2). Three of the *E. freibergi* PcP190 sequences are highly similar to the PcP190 sequences of *Physalaemus* and PcP-1a sequences of *Pseudis*, even with respect to the hypervariable region (Figure 2). The remaining ten sequences, however, differ from those sequences in a 26 nucleotide-region at the beginning of the hypervariable region (Figure 2).

All species from the Edentulus clade showed a highly similar hybridization pattern with the PcP190 probe. PcP190 satDNA was mapped to a pericentromeric region of the the short arm of the chromosome identified as 3 in *E. freibergi* and *E. petersi* and identified as 5 in *Engystomops "magnus"* (Figure 3A-C). In addition, clusters of PcP190 were also detected near the centromere on the long arm of chromosomes 3 and 5 of *E. petersi* and *E. "magnus"*, respectively (Figure 3B,C).

Chromosome pairs 3 of *Engystomops freibergi* and *E. petersi* are very similar in morphology but they deeply differ from pair 3 of "*E. magnus*". Based on classical cytogenetic methods, the homeology between pair 3 of *E. freibergi* and *E. petersi* and pair 5 of "*E. magnus*" was proposed (Targueta et al., 2010), which was corroborated by the presence of a 5S rDNA site on the pericentromeric region of the short arm of these chromosomes (Rodrigues et al., 2012). Here we provide additional data to corroborate this homeology hypothesis, as chromosomes 3 of *E. freibergi* and *E. petersi* and chromosome 5 of *E. "magnus"* share the presence of PcP190 sites on both arms.

In contrast to the Edentulus clade, the karyotypes of the species of the Duovox clade are more similar to one another with respect to chromosome morphology, NOR position and heterochromatin distribution (Targueta et al., 2012) and they diverged more in relation to the location of PcP190 (Figure 3D-H). In the karyotypes of *E. montubio* (Figure 3D), *E. randi* (Figure 3F) and *E. guayaco* (Figure 3G), the PcP190 probe detected a pericentromeric region in both arms of chromosome 3. In the karyotypes of *E. randi* and *E. guayaco* (Figure 3F,G), the probe also mapped one pericentromeric region on the long arm of chromosome 5. In contrast, the accumulation of PcP190 sequences was detected only on a pericentromeric region on the long arm of chromosome 5 in *E. coloradum* (Figure 3E), whereas in *E. pustulatus* the PcP190 probe detected the pericentromeric region on both arms of chromosome 1, a

pericentromeric region on the short arm of chromosome 3 and a pericentromeric region on the long arm of chromosome 4 (Figure 3H).

Figure 3. Chromosome mapping of PcP190 sequences in *Engystomops* species. In FISH essays, PcP190 probes were labeled with dUTP-digoxigenin and detected using anti-digoxigenin coupled to rhodamine, and the chromosomes were stained with DAPI. **A.** *E. freibergeri*. **B.** *E. petersi*. **C.** *E. "magnus"*. **D.** *E. montubio*. **E.** *E. coloradorum*. **F.** *E. randi*. **G.** *E. guayaco*. **H.** *E. pustulatus*. In **C**, the karyotype of *E. "magnus"* is stained with Giemsa for a better visualization of chromosome morphology, and chromosome pair 5 from two metaphases hybridized with PcP190 probe are shown. Note the similarity between chromosome 5 of *E. "magnus"* (**C**) and chromosome 3 of *E. freibergeri* (**A**) and *E. petersi* (**B**) with respect to morphology and location of PcP190 sites. See discussion about the possible homeology between pair 11 of *E. "magnus"* and sex chromosome pairs of *E. freibergeri* and *E. petersi* in Targueta et al. (2010). Bar: 4 μm.

Table 2. Genetic similarity (in percentage) between the conserved region of the complete PcP190 sequences isolated from *Engystomops freibergeri* (present work) and those obtained from species of *Physalaemus* (Vittorazzi et al., 2011, 2014a, 2016), *Crossodactylus gaudichaudii* (Vittorazzi et al., 2014a), *Leptodactylus latrans* (Vittorazzi et al., 2014a), and *Pseudis tocantins* (Gatto et al., 2016), grouped according to their hypervariable region. Only conserved regions of complete monomers were considered in this analysis. PcP-1b and PcP-6 sequences of *Pseudis tocantins* were not included because no complete monomer is available

Figure 4. Chromosomal sites of PcP190 satDNA and 5S rDNA in *Engystomops*. The phylogenetic relationships in this genus are shown in the cladogram derived from the phylogenies inferred by Ron et al. (2010) and Funk et al. (2012) and ideograms show the hybridization sites of the PcP190 probe (red), type I 5S rDNA probe (blue; data obtained from Rodrigues et al., 2012) and type II 5S rDNA probe (green; data obtained from Rodrigues et al., 2012 and unpublished data) in each species. Note that type I 5S rDNA and PcP190 signals co-localize in *E. freibergi*, *E. petersi* and *E. "magnus"*. Because chromosomes 5 and 6 from species of the Duovox clade are very similar in size and centromeric position, simultaneous hybridization with the type II 5S rDNA probe and the PcP190 probe was needed to ensure that these probes detected distinct chromosomes. Based on a combined analysis of the phylogenetic and cytogenetic data, we may infer that the PcP190 cluster of chromosome 3 was lost in *E. coloradurum*. With respect to the PcP190 site of chromosome 5, one possible interpretation is that this PcP190 cluster was lost in *E. montubio* after having arisen in the common ancestor of *E. montubio*, *E. randi*, *E. guayaco*, and *E. coloradurum*. However, another hypothesis equally parsimonious is that a PcP190 cluster has arisen independently in chromosome 5 of *E. randi* and chromosome 5 of the common ancestor of *E. guayaco* and *E. coloradurum*.

Compiling all of the information regarding 5S rDNA and PcP190 sites on the karyotypes of *Engystomops* species (Figure 4), we can note that, at least in *E. freibergi*, *E. petersi*, and *E. "magnus"*, the type I 5S rDNA co-localizes with PcP190 clusters on the short arm of chromosome 3 (Rodrigues et al., 2012), as was also observed in *Physalaemus cuvieri* (Vittorazzi et al., 2011) and *P. ephippifer* (Nascimento et al., 2010; Vittorazzi et al., 2014a). This observation may contribute to the proposal that the origin of PcP190 satDNA occurred in an ancestral chromosome carrying 5S rDNA. Heteromorphic sex chromosomes X and Y are observed in *Engystomops freibergi* and *E. petersi*, and possibly heteromorphic Z and W chromosomes occur in *E. coloradurum* (Targueta et al., 2010; 2012), but none of them had

clusters of PcP190 satellite DNA revealed by FISH (fluorescent *in situ* hybridization). In these cases, sex chromosome differentiation did not involve this satDNA, in contrast to what could be inferred for *Pseudis tocantins* (Gatto et al., 2016) and *P. ehippifer* (Vittorazzi et al., 2014a).

5. SEX CHROMOSOMES IN ANURA

5.1. Sex Determination in Anurans: More Questions Than Answers

Genetic sex determination is a widely observed phenomenon in nature, mainly in animals and some plants, but only few genes are known for this function. In placental and marsupial mammals, the sex determination gene (SDG) is the gene *SRY* (sex determination region Y), a gene from the *SOX* gene family and a paralogue of the gene *SOX3* (Berta et al., 1990; Sinclair et al., 1990; Goodfellow & Lovell-Badge, 1993; Graves, 2008). In monotreme mammals, the candidate SDG is the gene *AMH*, which is located on the Y₅ chromosome (Cortez et al., 2014). For birds, characterized by female heterogamety, the SDG is the *DMRT1* (doublesex and mab-3-related transcription factor 1) gene, which is present on chromosome Z but absent on chromosome W, so that sex determination in avian species occurs by dosage of this gene (Nanda et al., 2000; Nanda et al., 2008; Smith et al., 2009). For non-avian reptiles that possess genetic sex determination, no candidate SDG is known to date. For fish species, there are two SDGs already characterized: the *DMY* gene, found in *Oryzias latipes*, a paralogue of the gene *DMRT1*; and the *AMHR2* gene, found in *Takifugu rubripes* (Paul-Prasanth et al., 2006; Matsuda et al., 2007; Graves & Peichel 2010).

For frogs, the only known SDG is the gene *DM-W*, a paralogue of *DMRT1* found on the W chromosome of *Xenopus laevis* (Yoshimoto et al., 2008; Mawaribuchi et al., 2017). *DM-W* probably arose from a duplication of *DMRT1* after the allotetraploidization event that occurred in the *X. laevis* lineage (Mawaribuchi et al., 2017). The gene *DM-W* is present in species closed related to *X. laevis*, such as *X. clivii*, *X. gilli*, *X. largeni* and *X. pygmaeus*, but it is absent in other species of the genus *Xenopus*, as in *X. tropicalis* and *X. muelleri* (Bewick et al., 2011). However, there is no evidence that *DM-W* is the SDG in all *Xenopus* species that possess it (Bewick et al., 2011). Recent studies identified sex-linked sequences in *X. borealis* that do not correspond to the *DM-W* gene and also inferred this species as the sister taxon of *X. clivii*. Because *DM-W* is present in *X. clivii*, and based on interspecific phylogenetic relationships, Furman & Evans (2016) suggested that *DM-W* arose as a sex-determining trigger in the ancestor of the group that includes *X. borealis*, *X. clivii*, *X. laevis*, *X. largeni*, and *X. allofraseri* and that *X. borealis* bears a new sex determination system that is derived with respect to the *DM-W*-based system.

In the ranid *Glandirana rugosa*, the *Sox3* gene was mapped to the sex chromosomes and has been considered as a candidate gene for sex determination, but its function is not yet elucidated (Uno et al., 2008; Miura & Ogata, 2013). Other candidate sex-determining gene is the *Dmrt1* found in some tree frog species (Dufresnes et al., 2015 and references therein).

These interesting findings concerning sex determination in frogs make evident how complex and diverse is this. Further studies on this issue will be certainly very elucidating as different sex determination systems, either with female and male heterogameties, are present in this group.

5.2. Sex Chromosome Differentiation

In organisms with genetic sex determination, the sex chromosomes harbor the sex determination gene that will trigger gonad development, in such a way that the heterogametic sex may be the male, such as in mammals (female: XX/male: XY), or female, such as in birds (male: ZZ/female: ZW) (for review, see Graves, 2008 and Schartl et al., 2016). Although sex chromosome differentiation has specific particularities in distinct lineages, some steps are common among all animals and plants that possess sex chromosomes, with the first one being the acquisition of a sex determination locus and the arrest of recombination in that region (Muller, 1964; Ohno, 1967; reviews in Graves, 2006, 2008). Suppression of recombination prevents breakage in sex determination linkage, allowing for the fixation of mutations on the chromosome exclusive of heterogametic sex (Y or W) (for review, see Graves, 2008 and Bergero & Charlesworth, 2009). Accumulation of heterochromatin by the amplification/invasion of repetitive DNA elements is a common consequence of this process, and it may also enhance the arrest of recombination between X/Z and Y/W, leading to higher levels of heteromorphism of these chromosomes (Singh et al., 1976, 1980; Charlesworth et al., 2005; Steinemann & Steinemann, 2005). In the final stages of sex chromosome differentiation, Y/W chromosomes may undergo a degeneration process, reducing in size and harboring only few genes involved with sex differentiation and/or reproduction (see Steinemann & Steinemann, 2005; Graves, 2008).

In anurans, both female and male heterogameties are present and the occurrence of heteromorphic sex chromosomes is rare. To date, among the already karyotyped anuran species, 21 species with XX/XY and 24 species with ZZ/ZW systems present heteromorphic sex chromosomes (see review by Schmid et al., 2012; Saba & Tripathi, 2014; Patawang et al., 2014; Sangpakdee et al., 2017). In addition, heteromorphic sex chromosomes were already found in multiple sex chromosome systems (derived from Y-autosome fusions) in species of the genera *Pristimantis* and *Strabomantis* (family Craugastoridae) and in *Eleutherodactylus cavernicola* (family Eleutherodactylidae) (Schmid et al., 1992, 2002a, 2003, 2010). Another uncommon sex chromosome system occurs in *Leiopelma hochstetteri*, as females has a supernumerary chromosome, denoting a 00/0W sex determination system (Green, 1988).

In addition to the diversity in sex chromosome systems, a high diversity is also observed with respect to the level of sex chromosome heteromorphism. In some cases, sex chromosome heteromorphism can be revealed only after employing specific techniques. In some anuran species, for example, the sex chromosomes can only be distinguished by differential replication patterns (Schempp & Schmid, 1981; Odierna et al., 2007). The sex chromosomes of *Xenopus laevis* can be differentiated cytogenetically only by mapping the *DM-W* gene onto chromosome W by *in situ* hybridization (Yoshimoto et al., 2008). The sex chromosomes of the bufonid *Rhinella marina* were identified by CGH (Comparative Genomic Hybridization) (Abramyan et al., 2009), and some species of the genus *Hyla* had a XX/XY sex determination system recognized only by linkage map analysis (Berset-Brändli et al., 2007). On the other hand, some species present highly differentiated sex chromosomes that differ both in morphology and molecular constitution. In *Pristimantis euphronides* and *Pristimantis shrevei*, for example, the Z chromosome is smaller than the W chromosome, which is almost entirely heterochromatic (Schmid et al., 2002a). In *Pseudis tocantins*, the submetacentric W chromosome is larger than the metacentric Z chromosome because of the presence of an amplified heterochromatin in Wq enriched for PcP190 satellite DNA (Busin et al., 2008; Gatto et al., 2016). In addition, these

sex chromosomes differ with respect to the NOR, which is interstitial in Zq and pericentromeric in Wq (Busin et al., 2008).

In most cases, however, intermediate stages of sex chromosome differentiation are noted. In some species, sex chromosomes are similar in size and centromeric position, but differ in heterochromatin accumulation and can be easily identified by C-banding (as in *Proceratophrys boiei* - Ananias et al., 2007, Amaro et al., 2012; in *Eupsophus roseus* - Iturra & Veloso, 1989; in *Gastrotheca pseutes* - Schmid et al., 1990; among several others). In other cases, sex chromosomes that are similar in size, centromeric position and heterochromatin amount can be distinguished by NOR location (as in *Dryophytes femoralis* – *Hyla femoralis* in Schmid & Steinlein, 2003; and possibly in *Engystomops coloradum* (Targueta et al., 2012). There are also cases in which sex chromosomes show similar sizes but differ with respect to centromeric position (as in *Eleutherodactylus johnstonei* – Schmid et al., 2010; and in *Pseudopaludicola saltica* – Duarte et al., 2010) or with respect to centromeric position and additional features, such as C-band distribution (as in *Eupsophus miguelli* and *Eupsophus insularis*, whose X chromosome is telocentric and possesses centromeric heterochromatin, while the Y chromosome is metacentric and lacks the centromeric positive C band – Iturra & Veloso, 1989; Cuevas & Formas, 1996). Differences in size between X/Z or Y/W have also been reported for several other species (reviewed by Schmid et al., 2012).

Because of the presence of different levels of sex chromosome heteromorphism, the frogs are an interesting group for studies on sex chromosome differentiation.

5.3. Sex Chromosome Turnover and Occasional Recombination between Sex Chromosomes

Transition between female and male heterogamety is very common in amphibians and may be observed even within the same genus. Evans et al. (2012), using tools for ancestral character state reconstruction and a molecular phylogeny proposed by Pyron & Wiens (2011), showed that there is no support to infer whether the ancestral heterogamety in frogs (or even in salamanders and amphibians) was female or male but they expanded the hypothesis first proposed by Hillis & Green (1990) that amphibians experienced several $XX/XY \leftrightarrow ZZ/ZW$ transitions. Over 30 cases of sex chromosome turnover in amphibians, including evolution of novel systems and reversals to ancestral conditions, were estimated by Evans and colleagues.

An interesting example of sex system transition is observed in *Glandirana rugosa*, as XX/XY and ZZ/ZW sex determination systems occur in geographically separated populations (Miura & Ogata, 2013 and references therein). The West-Japan and East-Japan geographic groups present homomorphic subtelocentric X and Y chromosomes, but they differ in morphology between the geographic groups, as the sex chromosomes of East-Japan specimens present a smaller short arm (Miura & Ogata, 2013 and references therein). Heteromorphic sex chromosomes are found in three other geographic groups, named the XY, ZW and Neo-ZW groups (Miura & Ogata, 2013 and references therein). Based on the analysis of mitochondrial DNA, allozymes, sex-linked genes and experimental reproductive crosses, two independent transitions from XX/XY to ZZ/ZW system could be inferred, one creating the ZW group and another giving rise to the Neo-ZW group. It is also very interesting to note that the metacentric X chromosome of the XY group and the metacentric W chromosome of both the ZW and neo-ZW groups are homeologous and probably originated from a pericentromeric inversion of the

sex chromosome of the East-Japan group. The XY group and the ZW group were created by hybridization events between West-Japan and East Japan groups, whereas the neo-ZW group was derived from re-hybridization of the XY group with the West-Japan group (Miura & Ogata, 2013 and references therein).

Transition between female and male heterogamety and translocation of the sex-determining locus to an autosome (which gives rise to a new sex chromosome pair without changing the heterogametic sex) have been frequently invoked to explain the prevalence of homomorphic sex chromosomes in some groups, such as anurans (see discussion in Volff et al., 2007; Perrin, 2009; Evans et al., 2012). Such events of sex chromosome turnover interrupt the differentiation between the previous sex chromosomes as new sex chromosome systems are achieved.

In addition to sex chromosome turnover, the fountain of youth model (Perrin, 2009) could also explain the prevalence of homomorphic sex chromosomes in anurans. According to this model, occasional recombination events between X/Z and Y/W near the sex-specific region would avoid accumulation of deleterious mutations (Muller ratchet) and arrest the degeneration process. Besides the evidence of recent events of recombination between the X and Y chromosomes of *Hyla arborea* (Berset-Brändli et al., 2008), which was already considered by Perrin (2009), new evidence of occasional sex chromosome recombination has been reported to species closely related to *H. arborea* and to *H. meridionalis* and *H. suweonensis* (Stöck et al., 2011, 2013a; Guerrero et al., 2012; Dufresnes et al., 2015). Species from other groups, such as the *Bufotes viridis* group, also agree with fountain of youth model, since sex-linked markers are not grouped by gametolog in phylogenetic analysis, but by species (Stöck et al., 2013b).

Both models (sex determining transitions and fountain of youth) are supported by strong empirical evidence, which suggests that they may act together, as argued by Dufresnes et al. (2015) for the Palearctic tree frog lineages. In this hylid group, both male heterogamety (as in *Hyla arborea* and closely related species, *Hyla meridionalis*, and *Hyla japonica*¹) and female (as in *Hyla suweonensis*) heterogamety are present, and evidence of occasional recombination events between sex chromosomes was found (Dufresnes et al., 2015 and references therein).

5.4. New Technologies in the Study of Sex Chromosomes in Anurans

Recently, next generation sequencing (NGS) has brought great progress to the study of sex chromosomes of several organisms. Different approaches using NGS have been employed and we summarize some of these as follows: (a) genome resequencing of heterogametic sex individuals and read mapping against a reference genome; (b) genome sequencing of males and females separately and comparing their *de novo* assemblies; (c) sequencing of isolated sex chromosomes obtained by laser capture microdissection or flow sorting; (d) transcriptome characterization of male and female gonads in several stages of embryonic development; and

¹ In *Hyla arborea* and its closely related species *H. intermedia*, *H. molleri*, and *H. orientalis*, the linkage group 1 (LG1) is sex linked. LG1 is also sex linked in *H. meridionalis* and in *H. suweonensis*, which presents female heterogamety. In contrast, in *H. japonica*, which is inferred to be the sister species of *H. suweonensis* and presents male heterogamety, LG1 is not sex linked. This linkage group is not sex linked either in *H. sarda*, *H. savignyi*, or *H. felixarabica* (Dufresnes et al., 2015 and references therein). An evolutionary proposal for sex chromosome turnovers in this group was presented by Dufresnes et al. (2015), who also discussed the fact that LG1 was co-opted for sex determination several times independently.

(e) genotyping by sequencing for genetic linkage map construction or identification of sex-linked markers.

Genome resequencing and read mapping against a reference genome have proven to be a reliable approach for investigating sex chromosomes, as in chicken (Chen et al., 2012) and in *Anopheles* mosquitoes (Hall et al., 2013). However, there are only three anuran genomes available to date: (a) *Xenopus tropicalis* (Hellsten et al., 2010); (b) *X. laevis* (Session et al., 2016) and (c) *Nanorana parkeri* (Sun et al., 2015). Since read mapping requires at minimum a good reference genome from a closely related species, currently this is not the best approach for anurans.

On the other hand, genotyping by sequencing (GBS; Elshire et al., 2011), which involves the sequencing of libraries of restriction fragments, has already shown interesting results in studies of sex chromosomes of frogs when data obtained from males and females are compared. Such an approach was satisfactorily used for the identification of sex-linked SNPs (single nucleotide polymorphisms) in *Xenopus borealis*, which helped Furman & Evans (2016) to propose that the DM-W gene is not the sex determination trigger in this species, although this gene is present in the other species of *Xenopus* closely related to *X. borealis*. In *Xenopus tropicalis* the data generated by restriction site-associated DNA sequencing (RAD-seq) together with the sanger sequencing of 65 amplicons supposedly linked to the sex-determining region suggested that the sex-specific region is small in this species, with large portion of its sex chromosomes corresponding to the pseudoautosomal region (Bewick et al., 2013). More recently, Brelsford et al. (2016) proposed a method for identifying sex chromosomes based on high-density linkage maps constructed from RAD-seq of individuals of a family without knowledge of offspring sexes. This method involves the identification of linkage groups (which correspond to the distinct chromosomes of the karyotype) and the construction of sex-specific maps based on the data obtained from the parents. The linkage group corresponding to the sex chromosome pair is inferred by comparing the number of informative markers per linkage group between the male- and female-specific maps. Because higher divergence is expected between the gametologs than between two chromosomes X (or Z), for the sex-specific linkage group a strong difference in the number of heterozygous markers between the male and female maps is expected, while for each autosome the number of informative markers is supposed to be similar between the two parental maps.

6. B CHROMOSOMES IN ANURA: GENERAL PROPERTIES AND EXCEPTIONS

The presence of supernumerary chromosomes, known as B chromosomes, is a characteristic found in the genomes of many eukaryote lineages, having been reported in all principal evolutionary branches, with many examples found in animals, plants, and fungi (for review, see Camacho, 2000). While we are still a long way from understanding the mechanisms involved in the origin, maintenance, and function of these chromosomes in genomes, they are characterized by three unifying features: (i) B chromosomes are dispensable to the principal genomic complement (A complement) and, when present, they may be limited to only a few populations of the species, and normally at low individual frequencies. Given this, new organisms in which these elements can be found are discovered sporadically. (ii) B

chromosomes are inherited irregularly, that is, in a non-Mendelian way. (iii) During meiosis, B chromosomes do not pair with any chromosome of the A complement. In anurans, 22 species belonging to twelve different families (Table 3) are known to have B chromosomes, but this represents only a very small proportion of the total number of anuran species karyotyped up until now.

As in other eukaryotes, the B chromosomes of anurans are typically minor genomic elements in comparison with the A chromosomes (Nur & Nevo, 1969; Schmid, 1978; Schmid et al., 1987; Baldisera et al., 1993; Rosset et al., 2006; Medeiros et al., 2006; Schmid et al., 2010; Hernández-Guzmán et al., 2011; Ferro et al., 2016). There are exceptions, however, such as in *Physalaemus feioi* (Milani et al., 2010), *Oreobates discoidalis* (Schmid et al., 2010), and *Hymenochirus boettgeri* (Mezzasalma et al., 2015), in which the B chromosomes are at least as large as the chromosomes of the A complement. Rarely, as observed in *Megaelosia massarti* (Rosa et al., 2003), the B chromosome is the largest chromosome of the karyotype.

These supernumerary elements behave independently of the A complement and at a local population level, as indicated by the fact that different populations of the same species may present distinctive morphologies or numbers of B chromosomes as observed among populations of *Boana albopunctata* (Gruber et al., 2007; Ferro et al., 2012 – as *Hypsiboas albopunctatus*) and *Odontophrynus americanus* (Rosset et al., 2006; Lanzone et al., 2008). Distinct chromosome morphotypes may coexist within a given population, and may even be found in the same individual in some cases (Ferro et al., 2016). Individuals may also present different combinations of these elements (Green, 1988; Green et al., 1993; Schmid et al., 2010). Schmid et al. (2010) documented, for example, four types of B chromosome in *Eleutherodactylus gundlachi*, all of which were telocentric, with two large elements similar in size to pairs 6 and 12 of the A complement of this species, while the other two B chromosomes are much smaller than those of the A complement. These authors documented specimens of *E. gundlachi* with up to 10 additional copies of the B chromosomes, but, when present, the large B chromosomes were only found in one copy in cells, whereas different random combinations of the small B chromosomes were found.

Given all of the different potential combinations of B chromosomes, some authors have attempted to define the limit for the number of copies of these supernumerary elements that a cell would be able to support. This type of analysis is complex, given that, in extreme cases, as many as nine or ten B chromosomes may be found in the same genome, as in the cases of *Gastrotheca espelitia* (Schmid et al., 2002b, Schmid, 2012) and *Eleutherodactylus gundlachi* (Schmid et al., 2010), respectively, reaching the unexpected number of 15 in *Leiopelma hochstetteri* (Green, 1988; Green et al., 1993). What number of B chromosomes a eukaryote cell can support and how the chromatin would be rearranged to accommodate this additional genomic content are questions that demand further attention, and these animals provide potentially interesting research models. The fact that segregation is non-Mendelian results in a spectrum of combinations of B chromosomes in a population, ranging from individuals who have no supernumerary elements to those that have a number of copies (for example, see Green, 1988; Green et al., 1993).

Table 3. Summary of the B chromosome systems described in Anura

Pipidae <i>Hymenochirus boettgeri</i>	1	S	m	C+	-	Mezzasalma et al., 2015

* maximum number of B chromosomes per cell. ** (S) B chromosomes undifferentiated; (D) B chromosomes vary in size and morphology; ¹ Polyploid species with inter-individual and inter-population variation;

Presence of NORs is indicated by a “+”, while the absence of NORs is indicated by a “-”. q = long arm; p = short arm; C+ = completely heterochromatic; C- = absence of heterochromatin blocks; cen = centromere; int = interstitial position; per = pericentromeric position; ter = terminal position in the chromosome; n.e = not examine.

The meiotic behavior of these supernumerary chromosomes is the key to their irregular segregation. By definition, B chromosomes do not pair with the chromosomes from complement A during meiotic prophase I, and the observation of univalent chromosomes in a species is one of the criteria used to confirm the presence of supernumerary elements in the genome. When more than one copy is present in the nucleus, these elements may pair with one another, presenting a bivalent (example in Ferro et al., 2016) or multivalent (example in Nur & Nevo, 1969) configuration. In other cases, however, these copies may remain univalent during meiosis I, as observed in male *Dendropsophus nanus*, which have three copies of euchromatic B chromosomes (Medeiros et al., 2006). The majority of B chromosomes, despite being unstable during meiosis, are stable during mitosis (example in Gruber et al., 2007; Ferro et al., 2016), although there are exceptions (as B_d chromosome described by Ferro et al., 2016).

In practically all cases of B chromosomes in anurans, C-banding reveals elements either partially (see, for example, Schmid, 1978; Gruber et al., 2007; Milani et al., 2010; Ferro et al., 2012) or completely heterochromatic (Green & Sessions, 1991; Schmid et al., 2002b; Schmid et al., 2010; Suaréz et al., 2013; Mezzasalma et al., 2015), a characteristic also observed in the B chromosomes of other vertebrate groups. This would appear to be related to the evolutionary dynamics of these chromosomes because as dispensable elements in the genome, they are under weak selection pressure, which may lead to the accumulation of repetitive sequences (Camacho, 2000). In some organisms, the analysis of the heterochromatin content of B chromosomes has revealed the accumulation of transposons and retrotransposons, and the presence of different families of repetitive DNA. In anurans, unfortunately, the description of the heterochromatin content of the B chromosomes has been limited to conventional banding methods, while their nucleotide content has been analyzed only using base-specific fluorochromes (Gruber et al., 2007; Milani et al., 2010; Ferro et al., 2012; Mezzasalma et al., 2015; Ferro et al., 2016). However, small amounts of heterochromatin were already reported for supernumerary elements of *Dendropsophus nanus* (Medeiros et al., 2006) and in *Megaelasia massarti* (Rosa et al., 2003), for example, which makes these species interesting models for the study of the DNA content of these elements.

The fact that the B chromosomes accumulate large heterochromatic segments does not necessarily mean that they are transcriptionally inert. With the ongoing advances in genomic methods, this has been shown empirically in the B chromosomes of plants, grasshoppers, and fish. The B chromosomes of some anuran species contain rDNA sites which are transcriptionally active in the genome and can be detected through the silver Ag-NOR method (Green & Sessions, 1991; Milani et al., 2010; Schmid et al., 2010; Schmid et al., 2012; Ferro et al., 2016). Two copies of rDNA were detected by FISH in one of the B chromosome types of *Oreobates barituensis* (Ferro et al., 2016), while only one copy was detected by the Ag-NOR method, providing direct evidence of transcriptional activity prior to the last cell cycle.

The molecular composition of the B chromosomes is the principal source of evidence for the formulation of hypotheses on their origin. Three principal hypotheses have been proposed to account for the appearance of these chromosomes: (i) intraspecific origin, (ii) byproducts of the process of differentiation of the sex chromosomes, and (iii) interspecific origin, as vestiges of hybridization events. In the case of the intraspecific origin, the principal assumption is the sharing of DNA sequences with the A chromosomes genome. As mentioned above, the fact that B chromosomes do not recombine with the A genome means that these elements are inherited clonally, which means that we would expect young B chromosomes of intraspecific origin to present greater similarities with the A chromosomes. This hypothesis has been used

to explain the origin of B chromosomes of a number of different groups of organisms. The supernumerary chromosome of *Sphaenohynchus dorsiae*, for example, contains a large block of telomeric repeats that occupy almost the whole of the B chromosome, which Suárez et al. (2013) found to be highly similar to the segment present in the homologs of pair 2 of *Sphaenohynchus lacteus*, which is absent from homeolog 2 of *S. dorsiae*. This evidence led the authors to suggest that the B chromosome of this species may have originated from this region of chromosome 2.

In the B chromosome system of *L. hochstetteri*, however, the comparison of the DNA sequences of the B chromosomes with those of the W chromosome revealed a high degree of similarity, which is consistent with the intraspecific origin of B elements from the diversification of the W sex chromosome of this species (Sharbel et al., 1998). Similar evidence of sex-chromosome derived B chromosomes has been found in *Characidium gomesi*, another species with a ZZ/ZW system (Pansonato-Alves et al., 2014).

The third hypothesis postulates that the B chromosomes are remnants of genomic hybridization events that have persisted in the genome. This hypothesis is normally the most difficult to validate, because it requires the confirmation of two fundamental aspects: (i) the sharing of specific DNA sequences between the B chromosome of one species and the A chromosomes from putative other species interbreed, and (ii) the occurrence of the two species within the same zone of sympatry. While a number of studies have attempted to prove the role of this mechanism in the origin of B chromosomes in anurans, no conclusive evidence of the process has been presented in any case.

While the origin of B chromosomes has been identified conclusively in some cases, most attempts to assess their homologies with the A chromosomes have failed, which may be a consequence of the independent evolution of B and A complements. In *Physalaemus feioi*, for example, the supernumerary chromosome has a large heterochromatin block on its long arm, which was exclusively detected by a probe derived from microdissected B chromosomes (Figure 5). No hybridization signal of this specific B probe was detected in the A complement, suggesting that some repetitive sequences are accumulated or exclusively present in this supernumerary chromosome. A similar situation has also been reported to the B chromosome of a Brazilian population of *Boana albopunctata*, which was entirely detected by a probe that did not hybridize to the A complement of this species (Gruber et al., 2014). In this case, the B probe detected small scattered regions on all chromosomes of another species, *Boana raniceps* (Gruber et al., 2014), which may correspond to sites of repetitive DNA sequences. Given the dynamic evolution of repetitive DNA (for review, see Feschotte & Pritham, 2007 and Plohl et al., 2008), the sharing of repetitive sequences should be analyzed with caution when assessing homology hypotheses. For this reason, the results observed by Gruber and colleagues should not be interpreted as a direct evidence of interspecific origin of the B chromosome of *B. albopunctata* (see discussion in Gruber et al., 2014).

Another interesting finding on the B chromosomes of anurans is the presence of these elements in the genomes of natural polyploid species. While B chromosomes are relatively common in polyploid plants (for review, see Palestis et al., 2004), up until now, *Odontophrynus americanus*, a South American frog, is the only polyploid vertebrate known to have B chromosomes (Rosset et al., 2006; Lanzone et al., 2008). Although these elements were rare in the *O. americanus* populations analyzed by Rosset et al. (2006) and Lanzone et al. (2008), this organism provides a potentially interesting model for the analysis of the origin and maintenance of these elements in the genome.

Figure 5. B chromosome of *Physalaemus feioi*. **A.** *In situ* hybridization of a probe derived from microdissected B chromosomes. On the right, DAPI image; on the left, merged image of DAPI and B probe. Note that no hybridization signal is seen in the A complement, whereas the long arm of the B chromosome is detected by the probe. **B.** B chromosome submitted to C-banding and DAPI staining (C-band+DAPI), *in situ* hybridized with telomeric probe (tel probe), stained with chromomycin A3 (CMA3), and silver stained (Ag-NOR). **C.** C-banded metaphase stained with DAPI. The chromosome preparations in **A** and **B** were obtained from the female specimen SMRP 371.28, whereas the metaphase shown in **C** was obtained from the male ZUEC 16249 (one of the specimens also analyzed by Milani et al., 2010). The B chromosome found in the specimen SMRP 371.28 differs from those described previously (Milani et al., 2010) by the presence of a pericentromeric NOR, although the specimens were all collected from Viçosa-MG, Brazil. ZUEC: Museum of Zoology, University of Campinas, Brazil. SMRP: Collection “Shirlei Maria Recco Pimentel”, University of Campinas, Brazil.

In conclusion, despite the general properties recognized among B chromosomes of the different anuran species, the evolutionary profiles of these enigmatic chromosomes are far from being completely understood.

ABSTRACT

Humans are daily exposed to a variety of potentially harmful agents in the air they breathe, liquids they drink, food they eat and products they use. Long-standing evidence of the bond between health and environment has led to the recognition for the need of sustainable development. On the other hand, there is an increasing global awareness of the inevitable limits of individual health care and the need to complement such services with effective public health strategies. According to World Health Organization (WHO), cancer is a leading cause of death worldwide. Additionally, at least 200 000 people die every year from occupational or work-related cancers. Exposure assessment aims at prevention. Establishing the health effects of various activities and exposures requires information about the levels of exposure and the biological effects resulting from the interaction between the organism and the chemical agent. The resulting data provides a basis for designing effective prevention and mitigation strategies. Cytogenetic endpoints have long been applied in surveillance of human genotoxic exposure and early effects of genotoxic carcinogens. Assays measuring chromosomal aberrations (CAs), micronucleus (MN) and sister chromatid exchange (SCE) in lymphocytes are well-established techniques extensively used in human biomonitoring studies to assess DNA damage at the chromosomal level. The relevance of cytogenetic alterations as a cancer risk biomarker is further supported by epidemiologic data linking CAs and MN with cancer risk in human populations. Thus, the use of cytogenetic markers in human biomonitoring is of paramount importance due to its predictability regarding deleterious effects resulting from the exposure to environmental stressors.

Keywords: human biomonitoring, cytogenetic, chromosomal aberrations, micronucleus and sister chromatid exchange

AN INTRODUCTION TO HUMAN BIOMONITORING

Humans are exposed to several potential harmful agents in their daily life activities, in the air, water, soil, food and products they use [1]. Identification, evaluation and control of environmental hazards is of extreme importance to prevent the health effects of exposure to substances. Human biomonitoring is frequently used to provide early warning signals of excessive exposure, allowing the measure of the substances themselves, their metabolites or markers of subsequent health effects in body fluids or tissues [2]. Studying adverse health outcomes related to the environmental exposures (in the living and working environment) is a major societal challenge today.

Exposure can be assessed by biological monitoring, with measures of biological endpoints (biomarkers or biological indicators). Biological monitoring assesses the interaction of potential harmful agents with the biological systems by analyzing chemicals, metabolites, enzymes and other biochemical substances in tissues, body fluids or other accessible samples [1]. Other method used to protect human health in case of exposure to potential harmful substances is called environmental monitoring, that encompasses the measure of those substances in environmental matrices like air, water, soil, food, etc. Environmental monitoring is particularly important to the determination of the sources of exposure. The two methods, biological and environmental monitoring, complete each other and are commonly used simultaneously, since they provide different but complementary information [3, 4]. Nevertheless, human biomonitoring is essential because it allows a better estimation of the internal dose of a compound (dose really taken up) and consequently, its potential health risks, despite the route of exposure - inhalation, absorption through the skin, and ingestion.

Human biomonitoring depends on the use of biomarkers that are defined as a xenobiotically induced alteration in cellular or biochemical components or processes, structures, or functions measurable in a biological system or sample [5]. A good biomarker must be sensitive, specific, relevant, reproducible and measurable in the population. Biomarkers are traditionally divided into three main categories - biomarkers of exposure, susceptibility and effect. Biomarkers of exposure are defined as the compound, parent compound or its metabolites, or the product of an interaction between the xenobiotic and its target molecule or cell that is measured in a compartment within an organism (e.g., lead levels in blood; arsenic levels in hair). Biomarkers of susceptibility are indicators of an inherent or acquired capacity of an organism to respond to the challenge of exposure to a specific chemical (e.g., polymorphic genes of metabolizing enzymes). Biomarkers of effect are measurable biochemical, physiological, behavioral, functional or other alterations within an organism induced by the exposure and depending on the magnitude of the alterations can be recognized as associated with an established or possible health impairment or disease [1, 6].

Biomarkers of exposure are specific for the identification of the agent of exposure, while the biomarkers of effect are usually unspecific for the causative agent [6]. Although they are less specific in the identification of the agent of exposure, they can be more predictive of the induced toxicity. They are biological indicators of the response of the body to exposures indicating early sub-clinical changes, which can develop into pathological consequences [7].

Biomarkers of effect either indicate early processes that precede a disease or predict the development and presence of disease [8]. The cytogenetic biomarkers that are going to be addressed further in this chapter belong to the category of biomarkers of effect, and are extensively used tools in human biomonitoring studies, particularly in occupational studies, to evaluate the genotoxic potential of the exposure to hazardous chemicals [9].

CYTOGENETIC BIOMARKERS IN HUMAN BIOMONITORING

Cytogenetic biomarkers are extensively used tools in human population studies to assess the impact of environmental, occupational and medical factors on genomic stability [9]. Nowadays, the most used cytogenetic endpoints in human biomonitoring studies are chromosomal aberrations (CAs) and micronucleus assay (MN). The increased frequency of these indicators in exposed workers is a consistent finding in several studies [10-17]. Also, the interest in assays measuring these cytogenetic alterations has increased since they have been linked with cancer risk in human epidemiologic studies [18, 19].

One critical issue in the use of cytogenetic endpoints in human biomonitoring is the selection of the biological specimen to investigate [20]. These endpoints are usually assessed in readily available surrogate cells to estimate events occurring in target tissues and to provide early warning signals for adverse health effects. Despite the documented usefulness of non-blood cells (e.g., buccal, nasal, urothelial) in biomonitoring [21] the peripheral blood lymphocytes (PBLs) are the most frequently used cells in human studies. The major reason to use lymphocytes is because they can be damaged in any tissue/organ specific toxic environment, since these cells circulate throughout the body and have reasonably long life-span [22]. The preference in the use of lymphocytes is also given to the fact that they exist in large number in the human body and are relatively simple to harvest.

In this chapter we are going to review the mechanisms and methodology of the major cytogenetic endpoints used in human biomonitoring: CAs, MN and sister chromatid exchanges (SCEs). An overview of these cytogenetic assays can be observed in Figure 1.

Figure 1. Overview of the cytogenetic assays.

Chromosomal Aberrations (CAs): Mechanisms and Methodology

Chromosomal aberrations (CAs) are changes in normal chromosome structure or number that can occur as a consequence of exposure to chemicals or radiation [23]. Chromosome structural changes have been assessed for decades by CA assay in PBLs to evaluate the exposure to contaminants in occupational and environmental settings.

Structural CAs may be induced by direct DNA breakage, replication on a damaged DNA template, inhibition of DNA synthesis or other mechanisms (e.g., topoisomerase II inhibitors) [23]. The formation of structural CAs requires one or several double-strand breaks (DSBs). Mechanistic and morphological differences categorize these CAs in two types: chromosome-type aberrations and chromatid-type aberrations. Concerning the morphology, chromosome-type aberrations involve both sister chromatids of a chromosome or more chromosomes, and chromatid-type aberrations only one chromatid of one or several chromosomes [24]. Regarding the mechanism, chromosome-type aberrations and chromatid-type aberrations differ in the type of initial lesion (induced by different agents) and the DNA repair mechanisms that follow. Those lesions are commonly repaired by three main mechanisms: homologous recombination (HR), non-homologous end joining (NHEJ) repair and single-strand annealing (SSA). HR is an error-free process, highly accurate that precisely restores the original sequence at the break. NHEJ is an error-prone repair process that joins directly the two broken ends which usually leads to small-scale alterations at the break site. SSA mainly leads to the formation of interstitial deletions [25].

Chromosome-type aberrations are usually generated *in vivo* by S-phase independent clastogens in resting G₀/G₁ lymphocytes. After DNA synthesis and chromosome duplication, the aberrations formed are doubled and chromosome-type breaks and exchanges (e.g., dicentric and ring chromosomes) are seen in metaphase. The duplication originates symmetric lesions on both sister chromatids. They reflect DSBs that are incompletely repaired or unrepaired by NHEJ repair and SSA.

Chromatid-type aberrations arise predominantly *in vitro* during the S-phase of the cultured lymphocytes. These type of breaks and exchanges are the response to base modifications and single-strand breaks (SSBs) induced *in vivo* by S-phase dependent clastogens. DSBs are a consequence of these lesions during DNA replication. Incomplete or failed repair of these lesions by conservative HR will generate chromatid-type aberrations formation in a subsequent metaphase [26, 27]. Chromatid-type aberrations formation is the mechanism most likely to be applicable to human biomonitoring studies since it represents the common process by which clastogenic chemicals induce CA.

As previously mentioned, the detection of structural CAs in human biomonitoring studies is performed in lymphocytes using the CA assay. This assay is the most widely used and best validated because the mechanisms for CAs induction are better understood and most environmental toxic substances have been shown to induce structural CAs [22, 28]. In fact, the CA assay is recognized as one of key tests for genotoxic compounds, being its protocol defined by OECD guidelines for the testing of chemicals (OECD TG 473) [29].

Lymphocytes are cultured in the presence of a mitogen, for instance phytohemagglutinin (PHA), in order to stimulate cell division. A spindle inhibitor (e.g., colcemid, colchicine) is added to the culture after a determined period to stop the replication when cells are in the metaphase. A schematic of the assay is represented in Figure 2.

Figure 2. Schematic representation of CAs assay described by Roma-Torres et al. 2006 [31] and examples of microscopical observations.

Afterwards, the metaphase-arrested cells are ready for scoring. This method is not appropriate for the estimation of numerical CAs, since chromosome loss can occur. Numerical CAs are changes in normal chromosome number, a consequence of abnormal cell division. Cells are considered aneuploid when they contain extra (hyperploid) or missing (hypoploid) chromosome. These changes may occur due to damage to the mitotic spindle and associated elements, damage to chromosome sub-structures, alterations in cell physiology and mechanical disruption [26, 30]. The additional use of fluorescence in situ hybridization (FISH) methods that have higher sensitivity and efficiency, enables the detection of subtle aberrations, as chromosome-specific rearrangements and/or loss, that are not apparent when using the conventional Giemsa staining [24].

Micronucleus (MN): Mechanisms and Methodology

Micronucleus (MN) are extra-nuclear bodies resultant from damaged chromosome fragments and/or whole chromosomes that are not included in the daughter nuclei at completion of telophase during mitosis. The chromosome fragments or whole chromosomes lag behind during the segregation process in anaphase because they did not attach properly to the spindle. The DNA material is eventually enclosed by a nuclear membrane being morphologically similar to nuclei (with the exception of its smaller size) after conventional nuclear staining [32].

Chromosomal fragments can result from direct DNA breakage, conversion of SSBs into DSBs during replication, or inhibition of DNA synthesis [26]. Whole chromosomes are generally formed from defects in the chromosome segregation machinery, such as deficiencies in the cell cycle checkpoint genes, dysfunction of the mitotic spindle, defects in kinetochore or other parts of the mitotic activity [32]. MN formation can also be related to damage to chromosomal sub-structures, hypomethylation of centromeric and pericentromeric DNA or mechanical disruption [26, 33]. Hence, MN may represent a measure of both chromosome

breakage and chromosome loss, so an increased frequency of micronucleated cells can reflect exposures to clastogenic (e.g., structural CAs) or aneugenic (e.g., numerical CAs) agents.

The MN assay can also provide parameters of genetic damage [e.g., nucleoplasmic bridge (NPB) and nuclear buds (NBUDs)] apart from the chromosome breakage and loss. DSBs misrepair may result in the development of a dicentric chromosome and an acentric fragment. Typically, at anaphase the dicentric chromosome forms a NPB between the two daughter nuclei, when its centromeres are pulled to the opposite poles of the cell, and the acentric fragment results in a micronuclei [32, 33]. NBUDs are characterized by having the same morphology as a micronuclei, but they are attached to the nucleus by a narrow or wide nucleoplasmic connection [33]. The nuclear budding takes place during S-phase of the cell cycle and cells are sometimes referred as “broken egg” cells. Nuclear budding seems to be the mechanism by which cells remove amplified and/or excess DNA, being NBUDs considered a biomarker of gene amplification and/or altered gene dosage [32].

Once formed, a micronucleated cell can be eliminated by apoptosis, the MN can be expelled from the cell, retained in the cytoplasm or incorporated into the main nucleus. However, the post-mitotic fate of the MN and the micronucleated cell is still poorly understood [20].

Currently, MN are extensively used as genotoxicity biomarker and has found a place in human biomonitoring studies, being one of the best validated techniques to evaluate chromosomal damage in humans [34]. In fact, MN assay offers more advantages than SCE and CA assays - MN scoring is simpler, requires shorter training and is less time consuming.

MN frequency can be assessed in exfoliated epithelial cells (buccal, nasal mucosa, urine), erythrocytes [OECD TG 474 [35]] or in lymphocytes. The *in vitro* mammalian cell MN test protocol for testing chemicals, encompassing cultured primary human or other mammalian PBLs, was adopted in 2010 by the OECD (OECD TG 487) [36]. In human population studies, the PBLs are the most commonly used tissue and the most frequently used test the cytokinesis-block micronucleus (CBMN) assay. This assay has been extensively validated worldwide for assessing environmental effects on chromosome damage in blood and epithelial tissues in human populations. The MN frequencies can be influenced by age, sex, nutritional status or smoking habits [37, 38]. A schematic representation of the CBMN assay is presented in Figure 3.

Like the CA assay, CBMN assay is performed in cultured PBLs that have divided once and were stimulated to proliferate in the presence of a mitogen (PHA). MN can only be expressed in cells that have completed one nuclear division, and for that reason is necessary to differentiate these cells from resting cells to assess the cytogenetic damage [23]. Cytochalasin-B (actin-polymerization inhibitor) is added before the first mitosis to block the cytokinesis allowing the identification of the once-divided cells in culture (binucleated cells) and the cells that did not divide or escaped the blocking of cytokinesis (mononucleated cells). Of note that only the cells that completed one nuclear division during *in vitro* culture can express the damage inflicted *in vivo*. The presence of MN in binucleated cells corresponds to pre-existing *in vivo* chromosome damage that have accumulated in the DNA since the last replication and lesions expressed as MN during the first *in vitro* mitosis. In mononucleated cells, MN are a result of genomic instability accumulated over many years in stem cells and circulating lymphocytes. The CBMN test also provides information on the nuclear division index by the registration of mono, bi, tri and tetranucleated cells, offering useful information regarding the cytostatic

potential of exposures by the identification of compounds that stimulate or delay cell division [39].

Figure 3. Schematic representation of CBMN assay described by Costa et al. 2006 [12] and examples of microscopical observations.

The combination of the CBMN assay with FISH probes contributes to the higher specificity and sensitivity of the method, since it allows the differentiation of MN containing a whole chromosome (centromere positive MN), resulting from the action of aneugenic agents, or an acentric chromosome fragment (centromere negative MN), reflecting the exposure to clastogenic agents.

In conclusion, besides aneugenic and clastogenic events this assay can provide information on several genotoxic and cytotoxic markers, such as, NPB (marker of chromosome rearrangement), NBUDs (marker of gene amplification) and nuclear division index (estimation of cell division inhibition).

Sister Chromatid Exchanges (SCEs): Mechanisms and Methodology

Sister chromatid exchanges (SCEs) are the result of interchanges of DNA between two sister chromatids in a duplicating chromosome. These reciprocal DNA exchanges take place during the S-phase of the cell cycle, when DNA is duplicated, resulting in two identical daughter chromatids. The effective breakage of DNA in sister chromatids followed by the reunion of the chromatids with one another, apparently at the same location, results in the SCEs [40]. Even though the mechanism of formation of SCE is not completely understood, they seem to be a consequence of the replication of a damaged DNA template, possibly at the replication fork [26]. The likely pathway for SCEs formation involves the initial collapse of a replication fork when facing a previously existent gap or SSB in one parental strand [41]. Subsequently, the formation of a replication-associated DSB with one free end takes place, initiating the repair process by conservative HR with the invasion of the intact sister strand to serve as a template

for DNA synthesis. Resolution of the resulting Holliday junction by non-crossing over will follow, triggering the induction of SCEs [42] (Figure 4). Another possible mechanism for SCEs formation is the initial stall of the replication fork due to the existence of obstacles, namely adducts, on the DNA template. The cleavage of these intermediary structures by endonucleases will induce DSBs with one free end that can be further repaired by conservative HR as previously described, resulting in SCEs [42].

Figure 4. Mechanism of SCEs formation. A) Replication fork approaches a SSB. B) Collapsed replication fork; fork breaks; repair synthesis. C) 5' to 3' double-strand break resection. D) HR pathway, strand invasion. E) Resolution of the Holliday junction in the orientation shown by the arrows results in SCE, as illustrated by the grey/black color junctions in the new "parental" strands. F) The replication fork is restored (taken from Costa et al. 2013 [43]).

Taylor and coworkers were the first observing SCEs with the use of autoradiography on cells that underwent a cycle of triitated thymidine incorporation followed by a replication cycle in nonradioactive medium [44]. Nowadays, 5-bromo-2'-deoxyuridine (BrdU), an analogue of DNA thymidine, is used for a better visualization of the SCEs. A standard fluorescence assay is used based on differential staining of the sister chromatids after inducing cell division in the presence of BrdU [45]. BrdU is efficiently incorporated into the DNA during replication due to the closer resembles with thymidine. This technique takes advantage of the semiconservative nature of the DNA replication and when cells are cultured through a single replication cycle with the presence of BrdU in the medium, one DNA strand in each daughter chromatid is substituted by this thymidine analogue. After the second replication round the two sister chromatids differ in BrdU presence: one chromatid contains one substituted DNA strand, while both strands of its sister chromatid are substituted. The chromatids can be further differentiated with Hoechst dye, that fluoresces at lower intensity when bound to DNA substituted with BrdU than when bound to unsubstituted DNA [46]. Photosensitization with UV light is conducted, resulting in the selective degradation of the highly substituted chromatid, since it seems to preferentially break the bonds present in non-histone proteins of the chromatid containing more BrdU. Giemsa staining follows and the asymmetric distribution of BrdU-substituted DNA in sister chromatids can be observed by light microscopy, because brdU incorporation leads to a much weaker staining being the chromatid with more BrdU lighter in appearance [41]. SCE frequencies can afterwards be scored using a semi-automated computer-based metaphase finder. In Figure 5 a schematic representation of SCEs assay can be observed.

Figure 5. Schematic representation of SCEs assay described by Teixeira et al. 2004 [47] and examples of microscopical observations.

CAs, MN, SCEs AND RISK PREDICTIVITY OF HUMAN DISEASES

Environmental exposures related to our lifestyle, infections and the occupation that we have throughout our life are considered a major cause of cancer in humans. According to the World Health Organization (WHO), cancer is a leading cause of death worldwide, being responsible for 8.8 million deaths in 2015. Globally, one in six deaths is due to cancer. It has been estimated that 3 to 6% of all cancers in the world are resultant from occupational exposures. Additionally, at least 200 000 people die every year from occupational or work-related cancers [48].

Exposure assessment aims at prevention. Looking at these numbers, it is of extreme importance to identify hazardous environmental substances and predict the development of cancer. Thus, a great challenge in biomarker research is the identification of long-term risks of developing cancer and the identification of early markers of occupational and environmental toxicity. The use of cytogenetic markers in human biomonitoring is of paramount importance due to its predictability regarding deleterious effects in health related with exposure to environmental stressors. Regarding carcinogenicity, the most frequently used biomarkers reflect genotoxic effects. Accordingly, these cytogenetic endpoints have been applied either in the surveillance of human exposure or in the investigation of the genotoxic potential of new compounds by the U.S. National Toxicology Program (NTP) and the International Agency for Research on Cancer (IARC). Epidemiologic data linking high frequencies of CAs and MN in PBLs with cancer risk in human populations supports the relevance of cytogenetic alterations as cancer risk biomarkers [18, 19].

SCEs were efficiently induced by several mutagenic or carcinogenic agents, particularly those that result in covalent DNA adducts or interfere directly or indirectly with DNA replication [45]. This assay has also gained popularity when it was observed that the cells that derived from patients with Bloom's syndrome, characterized by a high propensity for cancer, exhibit a hallmark high occurrence of SCE [49] due to dysregulation of HR by a defective

helicase function [41]. Defects in HR process might be the cause of genetic instability, increased SCE and high incidence of cancer in early life associated with this disorder. Actually, increases in SCE frequency have been used as a biomarker in the clinical diagnose of Bloom's syndrome [41, 50].

SCEs is considered a good biomarker of effect to genotoxic/mutagenic agents, although no association between high SCEs frequencies and cancer risk was observed [18, 28, 51-53]. In the early 1990s, the preliminary reports from the Nordic Study Group on the Health Risk of Chromosome Damage mentioned the lack of association between the frequency of SCE and the incidence of cancer in humans [52, 54]. The results obtained in these initial studies were later confirmed in 1998 by an European cohort study [18] and in 2004 in a study from Bonassi and coworkers [53]. An association between SCEs level and cancer risk is difficult to evaluate because the baseline levels of SCEs are different among individuals and across studies [51]. Consequently, the use of SCE as biomarker for human biomonitoring has been declining, and CAs and MN are the preferred methods nowadays.

As previously mentioned, CAs have been associated with cancer risk prediction, being the most extensively used biomarker in human populations exposed to genotoxic agents [26]. The first reports regarding possible associations between the frequency of CAs and the incidence of cancer in humans emerged in the early 1990s, as for SCEs. Several studies with Italian and Nordic cohorts reported that the CAs levels in lymphocytes revealed to be predictive of overall cancer risk in humans [18, 52, 55, 56]. In fact, one of the latest studies mentioned, a report from 1998 of the European Study Group on Cytogenetic Biomarkers and Health, had the following results using both cohorts that comprised 3541 subjects examined between 1970 and 1988: subjects with higher levels of CAs presented an elevated standardized incidence ratio for cancer of 1.53 for the Nordic cohort and a mortality ratio of 2.01 for the Italian cohort demonstrating an increased cancer incidence in healthy individuals [18]. Another report for the referred European Group using both cohorts confirmed that the increased risk of cancer was related to high levels of CAs in lymphocytes, but independent of the exposure to carcinogenic agents [57]. Although, a subsequent study from Smerhovsky and coworkers that analyzed data from 3973 subjects reported a strong association between the frequency of CAs and the incidence of cancer in workers exposed to radon – an increase of 1% in the frequency of CAs was associated with an increase in cancer risk of 64% [58]. Nevertheless, the data collected in this study could not assess this association with exposure to other chemicals. Later, other study using the Nordic and Italian cohorts concluded that both chromosome-type aberrations and chromatid-type aberrations have the similar cancer risk predictive values [27], however some studies showed stronger association of chromosome-type aberrations with cancer risk predictivity [51]. A later study from 2007 of Boffetta and coworkers in a cohort with total of 6430 subjects from 9 laboratories in central Europe confirmed these previous results, observing relative risks of cancer of 1.78 and 1.81 for the medium and high tertiles levels of CAs [59]. Also, this study assessed the relation between the frequency of CAs and the risk of specific cancers and showed a relation between CAs and stomach cancer and possibly the colon and rectum cancers, regarding the lung and breast cancers the results were only suggestive of an association. A study from Bonassi and coworkers helped to clarify some of the referred issues, using a larger pooled analysis with 22 358 cancer-free subjects that underwent genetic screening and with follow-up time for cancer incidence of 10.1 years [60]. The following results were observed: an increased relative risk of cancer was found for high levels of CAs, this increase was mostly driven by chromosome-type aberrations, the strongest association was found for the stomach cancer and

the effect of CA levels on overall cancer risk was not altered by exposure. These results were in general consistent with previous studies. A recent study in patients diagnosed with colorectal, lung and breast cancer also reported that CAs serve as predictive markers of cancer but in this particular study for the colorectal cancer association, only chromatid-type aberrations were significantly elevated [61]. The results obtained in all studies highlight the importance of CAs as biomarkers of cancer risk prediction in humans.

MN can be a result of chromatid-type aberrations occurring during the replication of DNA on a damaged template or chromosome-type aberrations initiated before mitosis and duplicated at replication [26]. Hence, taking into consideration the cancer risk predictivity of CAs and the mechanistic similarities between CAs and MN formation, it was expected that MN would also be possible biomarkers of cancer predictivity [20]. In the 1990s the first studies performed in this regard found no relation between MN frequency in PBLs and the cancer risk in humans [18, 52, 56]. Nevertheless, later in 2007 Bonassi and coworkers reported that MN formation is associated with early events in carcinogenesis [19]. The results emerged from a cohort of 6718 individuals that were screened for MN frequency between 1980 and 2002 and a significant increase of all cancers incidence was found in otherwise healthy subjects with an elevated frequency of MN in PBLs. The link between MN induction in PBLs and cancer development was further confirmed by case control and meta-analysis studies [62, 63]. A significantly higher MN frequency was observed in lymphocytes of individuals who developed cancer within 14 years after blood sampling (cases; 4.7 ± 3.4 MN/1000 BN cells) as compared to those who were still cancer free at the end of the follow-up period (controls; 1.5 ± 1.7 ; $p < 0.0001$) [62]. Additionally, subjects with a high MN frequency (>2.5 MN/1000 BN cells) had an increased risk of cancer death when compared with those with low frequency of MN (≤ 2.5 MN/1000 BN cells). A meta-analysis with findings from 37 publications about the association between MN frequency in PBLs and the presence of cancer diagnosis revealed a 28 to 64% increase in the baseline MN frequency of untreated cancer patients when compared to cancer-free referents [63]. Other recent studies using the CBMN assay reported an association between the increased MN frequencies in lymphocytes and the risk of colorectal and bladder cancers [64, 65]. A study from Maffei and coworkers found an increase of MN frequency in PBLs of patients with colorectal cancer (16.82 ± 6.56) when compared to controls (8.00 ± 1.77) [64]. This report also mentioned that the MN frequency found for the control group was in accordance with the MN frequency of healthy controls, adjusted for age and gender, of their laboratory database (7.54 ± 1.74). Recently, an increased frequency of MN (9.51 ± 4.73 versus 7.73 ± 3.91) and NBUDs (5.06 ± 3.36 versus 3.99 ± 2.44) was observed in bladder cancer patients compared to controls [65]. In addition to the cancer predictivity of MN, other biomarkers of the CBMN assay (i.e., NPB and NBUDs) have been reported as stronger predictors of cancer risk [65-67]. All the recently accumulated data on the cancer predictive value of elevated MN frequencies makes the CBMN assay a good candidate for wide application in human biomonitoring studies.

In Figure 6 a chronological representation of the major findings regarding the aforementioned cytogenetic biomarkers and the cancer risk predictivity in humans can be observed.

Figure 6. Chronological representation of the major findings regarding cytogenetic biomarkers and cancer risk predictivity.

APPLICATION IN OTHER HUMAN CELLS

Other cell types widely used to assess the formation of MN in human biomonitoring studies are the exfoliated cells, such as buccal, nasal or urothelial cells. These non-blood cells have some advantages when compared with lymphocytes for the use in large human biomonitoring studies: are easier to collect by non-invasive procedures; and, in some cases, these tissues are the actual target of the carcinogenic agents of exposure. For instance, they are in immediate contact with genotoxic agents by inhalation and ingestion, also kidney and bladder cells are in contact with the metabolites of the agents of exposure [68].

An advantage for the use of these types of cells is the elimination of the culture step, since these are usually rapidly dividing tissues. Cells are collected (swabbed in the case of buccal and nasal cells and isolated from urine in the case of urothelial cells) and dropped or smeared into the slides and stained with the appropriate dye [69].

Increases in MN frequencies in exfoliated cells in response to specific exposures have been widely reported. Some examples are the increases in MN frequencies in buccal, nasal and urothelial cells of populations exposed to formaldehyde [70-74], arsenic [75-77] and smoking [78-82].

Apart from the use of these cells in occupational and environmental biomonitoring studies, they have also been related with risk predictivity of human diseases [83]. In 2000, Bloching and coworkers suggested that the use of MN assay in buccal mucosa could be important in the prediction of cancer risk in the upper aerodigestive tract [84]. Exfoliated buccal cells collected from breast and uterus of untreated cancer patients presented a significant increase in MN number when compared to control subjects [85]. A study performed in 45 cancer patients with lung, stomach or colorectal cancer found significant increases in micronucleate cells number in buccal mucosa of cancer patients when compared with healthy control subjects [86]. Patients with lung cancer presented the highest number of buccal cells with MN per 1000 cells [86]. A study from Bonassi and coworkers under the frame of the HUMAN MicroNucleus project on exfoliated buccal cells (HUMN_{XL}) was conducted combining data of buccal MN values of 5424 subjects from 30 laboratories with the aim of studying several conditions that could impact MN frequency [87]. Significant increases in MN frequency were observed for the majority of occupational exposures and also cancer diagnosis. Associations between elevated MN frequency was observed for oropharyngeal cancer, respiratory cancer and all the other cancers pooled together. Also, in this study no associations were found for elevated MN

frequency and neurodegenerative diseases [87]. A subsequent systematic review and meta-analysis from Bolognesi and coworkers focusing in the clinical application of the micronucleus test in exfoliated buccal cells suggests that the MN assay can be useful in the prescreening and follow-up of precancerous oral lesions [83]. Increased MN frequency was observed in oral and neck cancer patients and leukoplakia, a premalignant stage of cancer, when compared with controls. Besides, in this study, an increased MN frequency was observed for patients with Alzheimer's disease and Down syndrome [83].

The MN test in urothelial cells has also been used to address the possibility of the assay to be conducted as a diagnostic tool. An increased MN frequency in urothelial cells has been observed in cancer patients [88-90]. Arora and coworkers performed a study with 30 cases of urine samples, where 15 were reported as normal urothelial cells and the other 15 as atypical urothelial cells that later turn out as malignant. MN were only observed in atypical cells ($2.53 \pm 0.99\%$), whereas no MN was found in the control cases [88]. A study using MN test in urothelial cells was conducted in women diagnosed with cervix cancer. This study reported an elevated frequency of micronucleated cells in 72% of the cancer patients when compared to 16.7% of controls [89]. Another study observed an increased MN frequency in cervix cancer patients, and found a linear association between the mean MN count and the stage of cervix cancer [90].

These studies suggest that the MN test in exfoliated cells might be an important indicator for malignancy and other diseases. The use of this type of cells may be advantageous in screening programs for occupational and environmental exposures and also for other human diseases, especially given the non-invasive method for collecting the samples.

CONCLUSION

We are all exposed to several harmful agents in our daily life activities, being those exposures possibly responsible for health impairments in the future. Research focused on the development of integrated approaches regarding the health risk assessment of populations exposed to hazard compounds is of paramount importance. Thus, genotoxicity biomarkers used in environmental and occupational health have been increasingly applied in human population studies.

Cytogenetic biomarkers are the most frequently used endpoints given their sensitivity to measure exposures of genotoxic agents and their role as early cancer risk predictors. These biomarkers are usually measured in lymphocytes, as the cytogenetic damage present in PBLs reflects cumulative exposure events and possible health consequences, as carcinogenesis, which can be related to chronic genotoxic exposure. CAs are the most validated biomarker in this regard although time-consuming. On the other hand, MN assay is a very promising alternative that is more appropriate for human biomonitoring, since it offers an easier technical procedure than SCE and CA assays, and has also been widely associated with cancer risk predictivity in several studies.

In order to efficiently use these cytogenetic endpoints in human biomonitoring is important to be aware of the need for the biomarkers to be validated and to have good protocols and sufficient technical expertise in the laboratories that conduct the assays.

One of main issues concerning cytogenetic biomarkers is the interpretation of altered levels of these indicators at individual level. Traditionally, risk predictions are only valid at a group level and therefore effect of inter-individual variability is removed. Hence, it will be important to conduct further research regarding the alterations on these endpoints at individual level.

Cytogenetic biomarkers such as SCEs, CAs and MN are extensively used as early predictors of clinical disease that can contribute to the implementation of new effective disease prevention policies in occupational and environmental settings. Further human biomonitoring studies encompassing cohorts with larger populations should continue to be conducted with the aim of obtaining a possible cut-off/control level that might be indicative of cancer/exposure risk prediction.

Chapter 56

COMPLEX KARYOTYPES AND THEIR DETECTION IN HEMATOLOGIC MALIGNANCIES: THE ONGOING ROLE FOR CLASSICAL CYTOGENETICS

Helena Urbankova*, PhD

Department of Hemato-Oncology, Faculty of Medicine and Dentistry, Palacky
University Olomouc and University Hospital Olomouc, Olomouc, Czech Republic

ABSTRACT

The great era for classical cytogenetics started sixty years ago with the description of the twenty-three pairs of human chromosomes (Tjio and Levan, 1956) and the discovery of the Philadelphia chromosome, the first known chromosomal defect associated with a specific type of cancer (Nowell and Hungerford, 1960). Since then many recurrent chromosomal aberrations linked to specific hematological malignancies have been detected. The vast majority of these abnormalities can be detected by modern molecular genetic methods so it might seem there is no longer a need for microscopy. However, there is still a significant portion of hemato-oncologic patients for which the classical cytogenetic investigation is appropriate, i.e., cases with complex karyotypes. Complex karyotypes are characterized by the presence of three or more unrelated chromosomal aberrations co-existing in a single clone. Their occurrence is associated with adverse outcomes across the entire spectrum of hematologic malignancies. These aberrations are also a powerful diagnostic indicator for molecular targeted therapies, allogeneic stem cell transplantation or other generally more aggressive treatment strategies. Since the presence of complex karyotypes would be missed when using only molecular genetic methods, this highlights the irreplaceable role of classical cytogenetics as a first-tier analysis for the evaluation of complex structural chromosomal abnormalities in hemato-oncologic patients. Ideally, classical cytogenetics is then followed by more precise molecular genetic methods to identify specific chromosomal aberrations more deeply. Here we focus on the complex

INTRODUCTION

Genomic Instability and Chromosomal Aberrations

Genomic instability and the creation of chromosomal aberrations is a hallmark of many types of cancer, including hematologic malignancies. Such genetic instability results in the deregulation of basic cell functions such as proliferation, growth, cell death, replication, angiogenesis, etc. (Hanahan & Weinberg, 2011). The molecular cause of genomic instability in hematologic neoplasms remains unclear, but according to recent sequencing studies, the so called mutator hypothesis seems to be flawed. Instead the sequencing results suggest that the DNA repair genes are frequently free of mutations before therapy. More likely, the mutation status of several other genes appears to be important: the tumor suppressor gene *TP53*, the ataxia telangiectasia mutated (*ATM*) gene and the cyclin-dependent kinase inhibitor 2A gene (*CDKN2A*). Mutations in these genes play a key role in the oncogene-induced DNA replication stress model, the currently most trusted theory of oncogene-induced DNA instability (Gaillard, Garcia-Muse, & Aguilera, 2015; Negrini, Gorgoulis, & Halazonetis, 2010). It is believed that the activation of oncogenes causes DNA replication stress and formation of DNA double strand breaks (DSBs) in precancerous lesions. The continuing generation of DSBs leads to genomic instability and together with defects in the DNA repair and checkpoint genes (*ATM* and *TP53*) results in cancer (Bartkova et al., 2005; Halazonetis, Gorgoulis, & Bartek, 2008). Nevertheless, the precise nature of oncogene-induced replicative stress is still not clear.

In the last 5 years, the deep sequencing of the cancer genomes revealed novel catastrophic mechanisms as the cause of complex chromosomal changes, i.e., chromothripsis, kataegis and chromoplexy. One or more chromosomes carry multiple and adjacent intrachromosomal rearrangements. Such aberrant chromosomes underwent deep fragmentation and further resealing and are no longer regarded as an independent item. More probably this deep fragmentation occurred during a unique catastrophic event (Palumbo & Russo, 2016; Stephens et al., 2011). Interestingly, this hypothesis contrasts starkly with previously described models of carcinogenesis as the consecutive accumulation of aberrations. Evidence for chromothripsis is found in different types of cancer, e.g., multiple myeloma, medulloblastoma, neuroblastoma and colorectal cancers. Moreover, in some studies, chromothripsis was associated with more aggressive types of cancer. This discrepancy needs to be further examined.

Generally, genomic instability generates point mutations leading to large chromosomal rearrangements and possibly results in complex changes affecting many chromosomes. As tumorigenesis is still believed to be a multistep process, we can distinguish between primary

and secondary abnormalities, which are changing and accumulating during cancer development (Heim & Mitelman, 1989).

Primary aberrations are connected with the earliest stages of cancer and are mostly found as sole karyotypic changes associated with the already described molecular consequence, e.g., activation of a particular oncogene or inactivation of a specific tumor-suppressor gene. However sometimes primary aberrations can present simply as submicroscopic mutations and may not be visible in the karyotype.

Secondary aberrations develop in cells with existing primary changes during later stages of the disease, probably as the consequence of the altered cancer cell metabolism (e.g., oxidative stress, defect checkpoints, mutations in DNA repair genes, etc.). Secondary aberrations are generally more numerous and less specific, but we still see non-randomness in many of them. It remains to be determined if all of them are pathologically relevant and have functional impacts on the course of the disease.

There are specific changes with known impacts on the course of the disease, but there is also a wide spectrum of aberrations with unclear functions. Elucidating this issue would require both an overview of all chromosomal aberrations that occur in cancer genomes as well as their analyses in large cohorts of patients. Important information can be lost when using only molecular genetic analyses, which either focus on particular targets and can therefore miss aberrations in other locations, or do not distinguish between different clones in a population of tumor cells. It is still uncertain whether the proposed scenario of primary and secondary changes is correct. It is well known that a primary change detected in one type of neoplasm can also occur as a secondary change in a different neoplasm and have a different clinical impact. Moreover, there is one more criterion: the aberrations must be clonal, meaning that they must be detected in at least two identical cells and, in the case of a loss of genetic material, even three cells. The significance of multiple chromosomal changes remains unexplained. Despite of this it is now clear that patients diagnosed with a hematologic malignancy that have three or more aberrations in the same clone (the so called complex karyotypes) are associated with adverse outcomes.

There are two types of chromosomal aberrations - structural and numerical. They lead to balanced/unbalanced relocations of chromosomal material or result in a loss or gain of entire chromosomes or chromosomal segments. Based on the type of aberration present, different detection methods are available.

Methods of Detection of Chromosomal Aberrations

Conventional cytogenetics is based on the chromosomes present in the metaphase stage of the cell cycle, when chromatin is highly condensed and a typical chromosome morphology is visible. Therefore cells (mostly from the peripheral blood, bone marrow or other biologic material) are grown short term in a culturing medium and arrested in a metaphase using a mitotic inhibitor. The cell suspension is further harvested and fixed using Carnoy's solution. The most frequently used technique to stain chromosome bands in hemato-oncology is G-

banding. The cell suspension is pretreated with trypsin and stained with a Giemsa staining solution. Twenty-three chromosome pairs can then be identified in humans based on their size, position of a centromere and a specific bright and dark banding pattern. The assembled karyotype is described using the International System for Human Cytogenetic Nomenclature (ISCN) 2016 (McGowan-Jordan J., Simons A., & Schmid M., 2016) and the detected abnormalities are defined. The advantage of this technique is that it allows the identification of balanced/unbalanced aberrations in a single cell at a low cost. Unfortunately, it has a relatively low resolution depending on the number and type of dividing cells and the quality of metaphase chromosomes, which can allow smaller aberrations to escape observation. Therefore, molecular cytogenetic methods based on complementary hybridization of a fluorescent labeled probe to patient's DNA were introduced.

These techniques brought a rapid improvement to the detection of chromosomal rearrangements. Fluorescence *in situ* hybridization (FISH) is the most frequently used technique. It was developed in 1982 by Langer-Safer et al., (Langer-Safer, Levine, & Ward, 1982) and its use for chromosome classification was described later in 1986 by Pinkel et al., (Pinkel, Straume, & Gray, 1986). FISH is able to detect and localize the presence or absence of a specific DNA sequence either on a particular chromosome or in an interphase nuclei without the need of metaphase chromosomes.

A large number of fluorescent probes targeting various sequences of the genome are now commercially available. FISH probes can be divided into three categories: locus specific, centromeric and whole chromosome painting probes. The selection of the appropriate probe for the detection of a specific chromosomal rearrangement associated with a particular type of hemato-oncologic disease depends on previous knowledge of the possible aberration. We can only routinely use a combination of two or three fluorochromes in a single hybridization and are therefore able to detect only a limited number of changes. Performing multiple hybridizations is time consuming and expensive. For these reasons using the FISH technique alone is not ideal for detecting multiple chromosomal aberrations and complex karyotypes. Similarly, the use of a singular molecular method such as allele-specific polymerase chain reaction (PCR), multiplex ligation-dependent probe amplification (MLPA), Sanger sequencing, etc., is also inadequate.

The multicolor FISH (M-FISH) approach is a much better tool. It was developed in the 1990s and published by Schröck et al., (Schröck et al., 1996) and Speicher et al., (Speicher, Gwyn Ballard, & Ward, 1996). This method is based on the complementary hybridization of probes to chromosomes in metaphase. The probes are labelled with a different fluorochrome combination specific to each chromosome. This technique allows the rapid and unequivocal detection of complex chromosomal rearrangements, whether they are balanced or unbalanced. Unfortunately the resolution of the M-FISH approach is also limited because of its correlation to chromosomes.

The introduction of a comparative genomic hybridization (CGH) was a key innovation. CGH is based on a competitive hybridization between the reference and tumor genomic DNA to the normal metaphase chromosomes. This approach could reveal unbalanced chromosomal aberrations by a single genome wide experiment (Kallioniemi et al., 1992). However, this

technique also has disadvantages: it's inability to detect balanced changes of genomes together with the relatively low resolution caused by the hybridization to chromosomes.

A few years later a variant of this technique was introduced: an arrayCGH (Pinkel et al., 1998; Solinas-Toldo et al., 1997). This method is also based on a competitive hybridization of the reference and tumor genomic DNA, but instead of binding to chromosomes it is applied to a chip with a spectrum of immobilized fragments of DNA. This enables the arrayCGH technique to detect genome wide unbalanced abnormalities with a high resolution defined by size and genome localization of the used fragments. ArrayCGH became a fast and reliable diagnostic tool for many cancer types, as well as hemato-oncologic diseases (Carter, Fiegler, & Piper, 2002; Fiegler et al., 2003; Vermeesch et al., 2007; Vermeesch et al., 2005). When combined with conventional cytogenetics and FISH, it provides a powerful methodology for the detection of complex chromosomal aberrations in hematologic malignancies (Knijnenburg et al., 2005; Kolialexi, Tsangaris, Kitsiou, Kanavakis, & Mavrou, 2005).

Next generation sequencing (NGS) strategies were developed recently (Sikkema-Raddatz et al., 2013). They are able to detect either balanced or unbalanced aberrations through the whole genome, but they have not added any major findings to the cytogenetic landscape of hematologic neoplasms. Moreover, they are quite expensive and require extensive biostatistical analysis. This is most likely the reason why these genome wide sequencing strategies are not currently widely used in diagnostic practice.

As it is well known that complex chromosomal changes impact prognosis in many hemato-oncologic diseases including the myelodysplastic syndrome (MDS), acute myeloid leukemia (AML), B-cell lymphoblastic leukemia/lymphoma (B-ALL), chronic myeloid leukemia (CML), chronic lymphocytic leukemia (CLL) and multiple myeloma (MM).

Unfortunately there is still a certain bias in defining a complex karyotype and its impact in various hematologic malignancies and there is a need for standardization (Peterson, 2017).

COMPLEX KARYOTYPE IN SELECTED HEMATOLOGIC MALIGNANCIES

Myelodysplastic Syndrome (MDS)

Myelodysplastic syndrome is a heterogeneous group of clonal bone marrow disorders characterized by impaired maturation of the hematopoietic cells associated with one or more peripheral blood cytopenias, which can also progress to acute myeloid leukemia (Vardiman, 2003). The current diagnostics follow the established WHO (World Health Organization) 2016 criteria based on histology, blast counts and cytogenetic findings (Arber et al., 2016). At the time of diagnosis, recurrent chromosomal aberrations are found in 40-70% of patients with primary MDS and these aberrations predict the rate of survival and the risk of leukemic transformation (Haase et al., 2007). The majority of these chromosomal changes are unbalanced (exhibiting loss of a part or an entire chromosome), but balanced translocations and complex

derivative chromosomes can also be detected. The most frequent cytogenetic aberrations include: del(5)(q) found in 10-20% of primary MDS, -7/del(7)(q) (10%), +8 (10%), del(20)(q) (5%) and others (Olney & Le Beau, 2001). All of these changes could be seen as solo aberrations or as a part of a complex karyotype, which has a big impact on the prognosis and the course of the disease. For example patients with isolated del(5)(q) have a good prognosis with a median survival of 4.8 years, whereas patients carrying the del(5)(q) as a part of a complex karyotype have a poor prognosis with early progression to AML. Complex karyotypes are observed in 10% of primary MDS and up to 90% of therapy-related MDS (Schanz et al., 2012). According to a Revised International Prognostic Scoring System for myelodysplastic syndromes (IPSS-R) (Greenberg et al., 2012), a complex karyotype in MDS is defined by the presence of three chromosomal changes in the poor prognostic group (with median survival 1.5 years), whereas the very poor prognostic group carry more abnormalities (median survival 0.7 years). Moreover according to the study of Göhring G. et al., (Gohring et al., 2010) aimed at the identification of prognostic factors in childhood myelodysplastic syndrome, it is important to define even the types of aberrations included in a complex karyotype. They defined the so called structurally complex karyotype, which is characterized by three or more chromosomal aberrations, at least one of which is structural. Patients with complex karyotypes but without structural rearrangement had a five-year overall survival similar to patients with normal karyotype, while patients with a structurally complex karyotype had a very poor outcome. Other authors studied the so called monosomal karyotype, which is defined by the presence of two or more autosomal monosomies or one monosomy with at least one structural abnormality. Such monosomal karyotypes seem to be associated with poor risk or very poor risk IPSS-R categories, but its prognostic value remains controversial. Other studies show that the impact of a complex karyotype as detected by conventional cytogenetics is increased by the presence of cytogenetically invisible mutations in the *TP53* gene, which can be detected by sequencing analyses. Patients with the *TP53* mutations and complex karyotype were associated with an extremely poor survival rate and a frequent early relapse, whereas outcomes were unambiguously better in the *TP53*-mutated patients without complex karyotype (Yoshizato et al., 2017).

In summary, not only is the presence of complex karyotype significant, but the number and the type of changes are also important considerations for establishing the diagnosis, prognosis and therapeutic strategies in patients with MDS. For these reasons the role of conventional cytogenetics remains pivotal in MDS. Cytogenetic results are very often complicated and biased, and therefore must be evaluated very carefully by a skilled cytogeneticist or a clinician experienced in cytogenetics in order to correctly interpret the karyotypic data. The combination of conventional cytogenetics with the results of molecular cytogenetic and genomic methods can produce more refined results and improve the risk stratification of MDS patients.

A. The complex karyotype detected by conventional cytogenetics (G-banding) of the bone marrow sample, marker chromosomes with unknown origin are present. The karyotype was described according to ISCN 2016: 43,XX,del(5)(q?),-6,-7,-8,-12,-15,-16,-17,?der(18),+4mar[cp24].

B. By M-FISH we proved the presence of the complex karyotype including both structural and numerical aberrations and we were able to specify more precisely particular abnormalities and marker chromosomes, e.g., monosomy 6, derivative chromosome der(7)t(7;17), trisomy 8 with two derivative chromosomes 8, etc. The karyotype was corrected: 43,XX,del(5)(q31q?35),-6,?der(7)t(7;17)(p?12;q?12),der(8)t(6;8)(?p;p?12)ins(8;15)(p?12;q?),der(8)(6qter>6q?13::12?>12?::8?>8?::15q?>15q?::6?>6?::15q?>15q?::8p11>8qter),+8,der(12)t(8;12)(?q;p?12)t(12;15)(q?24;q?),-15,-16,-17[10]

C. Interphase FISH with the locus specific probe XL Del(5)(q31) (MetaSystems, Germany) confirmed the deletion of 5q31 in 81% of cells. The orange labeled probe is designed to hybridize to the EGR1 locus at 5q31, whereas the green probe covers specific locus at 5p15 and functions as a control probe.

D. The result of metaphase FISH with centromeric probes specific for the centromeric regions of chromosome 7 (labeled in orange) and 17 (green) (Abbott Molecular, USA). The yellow signal is proving the presence of the dicentric chromosome dic(7;17). Based on this finding, which was not visible previously, the original description of der(7)t(7;17) was corrected for dic(7;17)(q11;p11) with consequently demonstrated deletion of the *TP53* gene.

E. ArrayCGH allowed us to detect already known changes as well as other previously hidden abnormalities and to precisely define the breakpoint regions and the aberrations of small sizes. In total we found 26 unbalanced genomic changes through the entire genome (SurePrint G3 ISCA CGH+SNP Microarray, 4x180K, Agilent), 21 losses (5q21.1q34, 6p25.3, 6p21.1, 6p12.3, 6p11.2q12, 6q12, 7q11.22q36.3, 8p21.3p12, 8p12p11.21, 12p13.33, 12p13.31, 12p12.3p11.22, 12q21.2q23.3, 12q24.11q24.33, 15q11.2q13.2, 15q21.3, 15q26.2, 16p13.3p12.3, 16p12.1, 16p12.1q24.3 and 17p13.3p11.2) and 5 gains (6p22.1p21.1, 6p21.1p12.3, 8p11.21q24.3, 15q21.3q26.2 and 16p12.1). Chromosomes are listed from the left to the right, from 1 to 9 and 10 to X and Y, respectively. The regions of gain are represented by the blue bars along the chromosomes, the regions of loss by the red ones.

All images were created in the Laboratory of Cytogenetics and Molecular Cytogenetics, Dpt. of Hemato-oncology Olomouc, Czech Republic, namely by: Kropackova J., Holzerova M. and Urbankova H.

Figure 1. Results of cytogenetics and molecular cytogenetic/genetic methods used to determine complex genomic aberrations in a patient with MDS diagnosed in our center.

Adult Acute Myeloid Leukemia (AML)

Acute myeloid leukemia is a neoplasm of the myeloid line of blood cells characterized by an accumulation of immature myeloid blasts in the bone marrow. This leads to an abnormal hematopoiesis and to a lack of differentiated granulocytes, monocytes, thrombocytes or erythrocytes. Based on the morphology, cytochemistry, immunophenotyping, genetic features and clinical characteristics, subgroups of AML can be defined with differing clinical relevance. There are currently seven subgroups of AML described (Arber et al., 2016; Swerdlow S. H., Campo E., Harris N. L., al., & 2008) and the majority of them has detectable clonal chromosomal aberrations. These aberrations, either numerical or structural, are summarized at the Mitelman Database of Chromosome Aberrations and Gene Fusions in Cancer (Mitelman, 2017). Cytogenetics provides strong prognostic information for prediction of the time of remission and post-remission therapy. Chromosomal abnormalities with good prognoses include t(8;21)(q22;q22.1), inv(16)(p13.1;q22) or t(16;16)(p13.1;q22) and t(15;17)(q22;q21). Patients carrying a normal karyotype are placed in the AML category with an average risk and require further molecular genetic analyses for accurate risk stratification. Patients with detected myelodysplasia-related changes del(5)(q), monosomies of chromosomes 5 or 7, translocations or inversions of chromosome 3, t(6;9), t(9;22), or abnormalities of chromosome 11q23 (*MLL* gene) have a particularly poor prognosis. Despite the fact that each specific category of AML has its own prognostic and treatment implications, for practical purposes antileukemic therapy at the diagnosis of AML is similar for all subtypes. The term complex karyotype in AML was introduced in the 1980s and at that time it was already observed to be associated with a poor prognosis (Berger et al., 1987; Levin, Le Coniat, Bernheim, & Berger, 1986). It was found that complex karyotypes are frequently characterized by the presence of certain chromosomal aberrations, for example monosomies of chromosome 5 and 7, deletions of 5q, 7q, 12p and 17p, moreover they are often associated with mutations of the *TP53* gene (Bowen et al., 2009).

The currently reported frequency of complex karyotypes with three and more unrelated chromosomal aberrations is 10-40% in all AML patients and increases with age (Stolzel et al., 2016). According to ELN (European Leukemia Net) recommendations, complex karyotype with three and more changes is classified as the adverse risk category. In comparison, the UK national classification system of Medical Research Council (MRC) for AML established the cutoff for adverse prognosis as the presence of at least four or more aberrations, and they consider the karyotype complex if it has at least five aberrations. Moreover, the definition of complex karyotype in AML is further complicated by the nature of its components. Breems et al., (Breems & Lowenberg, 2011) recently investigated the prognostic value of a monosomal karyotype, which is defined as either one autosomal monosomy and the presence of at least one structural aberration, or at least two distinct autosomal monosomies. They proved that the monosomal karyotype has a highly unfavorable impact on prognosis. On the contrary, it is well known that patients with complex karyotypes containing prognostically favorable aberrations, such as t(8;21), inv(16)/t(16;16) or t(15;17), remain in the good prognostic group despite the presence of the complex karyotype (Peterson, 2017).

Nevertheless, in general an increasing number of abnormalities included in complex karyotypes definitely worsens the overall survival of AML patients. Indeed, there is a need for a uniformly defined complex karyotype as an adverse-risk factor between different institutions. This issue should be figured out in the future by a survival analysis of a large multicenter cohort of AML patients with complex aberrant karyotypes.

Chronic Lymphocytic Leukemia (CLL)

Chronic lymphocytic leukemia is the most common type of leukemia in adults. It affects B-lymphocytes, which grow in an uncontrolled manner and accumulate in the bone marrow, peripheral blood and lymph nodes. In the past the use of conventional cytogenetics in the detection of chromosomal aberrations in CLL was not very successful due to neoplastic CLL cells having a very low mitotic activity, resulting in a lack of metaphase chromosomes in the cultures of peripheral blood cells.

Mitogenic stimulation of the CLL cultured cells with CpG-oligonucleotides and interleukin 2 was identified more than ten years ago as a reliable and reproducible tool that could obtain metaphase chromosomes and enable the assembly of a karyotype, even in CLL samples (Dicker, Schnittger, Haferlach, Kern, & Schoch, 2006). After an appropriate stimulation, chromosomal aberrations can now be detected in more than 80% of patients with CLL. The most frequent changes are deletions of the 13q14, 11q22, 17p13 and trisomy of chromosome 12 (Dohner et al., 2000). Deletions of the 11q22 (*ATM* gene) and 17p13 (*TP53* gene) are considered high risk factors with a poor outcome (Rigolin et al., 2017). The presence of complex aberrant karyotype was found in 10-20% of CLL patients (Haferlach, Dicker, Schnittger, Kern, & Haferlach, 2007; Mayr et al., 2006). Interestingly, many breakpoints are located in regions of recurrent losses in CLL, e.g., 13q14 and 17p13, which means conversely that complex karyotypes in CLL are often associated with 17p abnormalities (either deletions or mutations of the *TP53* gene) (Fink et al., 2006). In addition, the CLL subgroup with a complex karyotype seems to be strongly associated with an unmutated *IGVH* status and CD38 expression (Haferlach et al., 2007). According to recent studies, the complex karyotype became a strong independent predictive marker of rapid progression, resistance to therapy, early relapse and a short overall survival (Kujawski et al., 2008; Mayr et al., 2006; Puiggros et al., 2017; Van Den Neste et al., 2007).

Conventional cytogenetics represents the best tool for the detection of complex karyotypic abnormalities. Nevertheless, we also routinely use an interphase FISH technique which can estimate an aberrations in six precisely selected loci. The technique can provide information even in the absence of metaphase chromosomes or when the targeted abnormality is below the resolution of classical cytogenetics. We use commercially available probes for the numerical aberrations of 6q21, 8q24 (*MYC* gene), 11q22 (*ATM* gene), chromosome 12, 13q14, 13q34 and 17p13 (*TP53* gene) and rearrangement of the *IGH* gene (14q32). To complete the whole picture of a genome we perform an arrayCGH. The final karyotype is based on a combination of the results of all these methods.

Our data on complex karyotypes in CLL patients are in concordance with other authors (Kruzova L., 2017). We have detected complex karyotype in approximately 12% of untreated CLL cases diagnosed in our center and we have proven their adverse impact on the overall survival of patients. We did not observe any worsening effects due to the presence of *ATM* or *TP53* deletions as a part of a complex karyotype, which is in agreement with the finding of Thompson et al., (Thompson et al., 2015) and others. Moreover, we investigated particular chromosomal aberrations included in the complex karyotypes and their impact on the course of the disease in detail, but found no specific influence on the outcome in any way. Also we have suggested that patients with complex karyotypes are recommended for new treatments which are applied already in the first line of therapy.

Mantle Cell Lymphoma (MCL)

MCL comprises 3-10% of B-cell non-Hodgkin's lymphoma (B-NHL). Unlike other NHL types, nearly all cases are characterized by some level of the leukemic course of the disease with neoplastic cells detectable in the peripheral blood, as well as in bone marrow and other locations. This is advantageous for conventional cytogenetics, as the MCL infiltrated samples are available by non-invasive approach. The cytogenetic hallmark of the disease is the presence of t(11;14)(q13;q32), first identified by Banks et al., in 1992 (Banks et al., 1992), which leads to a juxtaposition of the *CCND1* gene to the *IGH* locus and to an overexpression of the cyclin D1. In approximately 20% of patients the translocation is a part of a complex karyotype (Gazzo et al., 2005) with the recurrent loss of der(11) and other changes. Complex karyotype is associated with a more aggressive disease and a shorter overall survival in MCL, but it is not clear if it can be regarded as an independent prognostic factor (Cohen et al., 2015; Sarkozy et al., 2014). This disease is quite rare and the data were mostly retrieved retrospectively. That is why our patients had been treated with different therapies and it is impossible to reliably compare their outcomes. We have analyzed cases diagnosed with MCL in our center from 2006 until now and have found complex karyotypes in 19% of patients (Obr A., unpublished data). Complex karyotypes were frequently accompanied by mutations in the *TP53* gene and a poor prognosis. We would need to analyze a larger cohort of patients treated with similar modern approaches to prove the independent prognostic impact of the presence of a complex karyotype in MCL.

Multiple Myeloma (MM)

Multiple myeloma is a cancer of the plasma cells - terminally differentiated B-lymphocytes which are normally responsible for the production of antibodies. Neoplastic plasma cells can form a mass in the bone marrow or soft tissue. Multiple myeloma is diagnosed based on the detection of abnormal levels of antibodies in the peripheral blood or urine, the finding of neoplastic plasma cells in bone marrow biopsy, and bone lesions revealed by medical imaging.

Cytogenetic analysis is an important part of MM diagnostics as chromosomal aberrations are powerful indicators of prognosis. Patients can be stratified into two prognostic categories according to the chromosome ploidy status and the rearrangements of the *IGH* gene. Generally, the hypodiploid group with $t(4;14)(p16;q32)$ or $t(14;16)(q32;q23)$ is associated with a high-risk disease, whereas the hyperdiploid patients with $t(11;14)(q13;q32)$ are considered a better prognostic group. During the disease progression the secondary chromosomal aberrations are developing. The most frequent are *MYC* rearrangements, deletions of the 13q, 17p, deletions of the 1p and/or amplification of the 1q. These secondary changes are characteristic of a highly proliferating and rapidly developing disease (Sawyer, 2011). Nevertheless, conventional cytogenetics is difficult because of the low level of bone marrow infiltration and the low mitotic index of plasma cells. Therefore cytogenetics is either unsuccessful or the results show normal karyotype in a majority of cases. In cases where abnormal karyotype is identified in a highly proliferative disease frequently multiple structural and numerical changes are found. Moreover patients often have various abnormal clones. Interphase FISH detects numerical and structural abnormalities in up to 90% of patients (Drach et al., 1995). To deal with a low infiltration of plasma cells in bone marrow samples, conventional interphase FISH was adapted to detect changes specifically in the plasma cells using a cytoplasmic light chain immunofluorescent labeling or purified CD138+ cells (Ahmann, 1998). The disadvantages of this approach are the restricted number of analyzed loci and lack of metaphase chromosomes, which subsequently also limits the detection of the complex karyotypes in MM. According to Nemec et al., (Nemec et al., 2012), metaphase cytogenetic analysis revealed the presence of complex karyotype in 19% of cases. Patients with a complex karyotype, translocation $t(4;14)$ and/or gain of the 1q21 locus had a shorter time to progression and a lower overall survival.

Recently, the arrayCGH technique has also found its place in the routine analysis of the genomic profile of the plasma cell, as it uses DNA from separated CD138+ cells. This method is able to identify multiple novel genetic aberrations that previously escaped detection. Nevertheless, the precise definition of the complex karyotype could not be matched in the majority of MM cases as we have no cytogenetic data proving a co-existence of various genomic changes in one clone. Perhaps this is the reason the complex karyotype is not discussed in MM as often as in other hematologic malignancies, even though it is probably present in a vast majority of them.

CONCLUSION

There is accumulative evidence that classical cytogenetics remains a valuable basic method for the analysis of genetic aberrations in the hemato-oncologic patients over decades. Previously it has been partially replaced by more precise molecular cytogenetics and genomic methods. However, with the recently recognized significance of the complex karyotypic changes in a wide spectrum of hematologic neoplasms, its role is again becoming crucial in the diagnostics and prognosis prediction. The correlation of cytogenetic results with clinical data and modern molecular genetic methods may provide clinicians with a broad and complex

overview of biological events taking place in tumor cells and may help them in therapy related decision making. Whereas in some hemato-oncologic diseases the definition of the complex karyotype is clear, in others it remains a topic of discussion. For example, in AML not only the number of unrelated clonal chromosomal aberrations but also its specific composition appear to be important. Complex karyotype is well defined and reported in CLL where it became an independent prognostic marker. On the contrary in other hemato-oncologic entities with problematic neoplastic infiltration of the bone marrow or peripheral blood (e.g., MM, B-/T-cell lymphomas other than MCL etc.), complex karyotypes are difficult to check with only conventional cytogenetics. Regardless of the scarcity of cytogenetic data, the results of other molecular cytogenetic methods show evidence of multiple genomic aberrations. In the future we can probably expect some adjustments to the definitions of certain questionable complex karyotypes in hematologic neoplasms.

In summary, conventional cytogenetics ideally complemented by other molecular cytogenetic and genomic methods remains an essential tool for the detection of the complex karyotype as an indicator of a poor prognosis across many hemato-oncologic diseases.

Agrários (MCENA), Universidade Federal de Viçosa, Campus Florestal– MG, Brasil

ABSTRACT

Initially identified as *Astyanax schubarti* on the basis of morphological characteristics, its chromosomal analysis revealed a unique diploid number in the genus. With 42 chromosomes and the impossibility of homologous pairing, the karyotype of the individual was compared to a set of haploid complements of *Astyanax schubarti* ($2n = 36$ chromosomes) and *Astyanax fasciatus* ($2n = 48$ chromosomes). Natural hybrids are rare. The viability of a hybrid between species with such chromosomal discrepancy may offer important hypotheses to explain the morphological, molecular, and cytogenetic diversity of the genus.

Keywords: hybridization, speciation, ecological genetics, evolutionary genetics

INTRODUCTION

Natural hybrids emerge following mating between individuals of two populations or distinct species, and they are identified on the basis of one or more hereditary characteristics (Downling and Secor 1997). The role of hybridization in the evolution of species remains controversial, but hybrid speciation, mainly in polyploid plants, is well documented (Mallet 2007). This phenomenon is common among species of teleost fish (Scribner et al., 2001; Salzburger et al., 2002; Meyer et al., 2005), but few studies have focused on the species of the Neotropical region, particularly in South America.

Piabas or *lambaris* in Brazil are representatives of fish belonging to the genus *Astyanax*, which is most abundant in South America (Géry 1977). Among the about 150 species already described, *A. mexicanus* stands out, and because it has cave populations with troglomorphic characteristics, it is used as a model species in developmental and evolutionary biology studies (Jeffery 2001). In South America, where most of the biodiversity of this genus occurs, chromosomal studies have identified several cryptic species in the last 25 years, including the groups *A. scabripinnis* ($2n = 46, 48$, and 50), *A. fasciatus* ($2n = 46$ and 48), and *A. bimaculatus* ($2n = 50$). In addition to the differences in diploid numbers, these groups also present variation in karyotype forms and in the presence of supernumerary chromosomes (Pazza and Kavalco 2007).

Most species of *Astyanax* with a characterized chromosome number have 46 to 50 chromosomes, except for *A. schubarti*, which has $2n = 36$ chromosomes, possibly resulting from Robertsonian translocations from an ancestral karyotype (Daniel-Silva and Almeida-Toledo 2005). *A. fasciatus* can present $2n = 46$ or 48 chromosomes in sympatric or allopatric populations (Artoni et al., 2006; Pazza et al., 2006; Pazza et al., 2008; Pansonato-Alves et al., 2013; Penteado et al., 2013; Pazza et al., 2016). In the Mogi-Guaçu River (upper Rio Paraná Basin), the largest variation in sympatric chromosomes is observed in the species, where in addition to the standard cytotypes (with adequate homology between the chromosomes) $2n = 46$ and 48 , specimens with $2n = 45, 46$ variants, and 47 chromosomes have also been observed, without supernumerary chromosomes (Pazza et al., 2006). These authors suggest that the chromosome number $2n = 48$ is common in the Mogi-Guaçu River basin, whereas the chromosome number $2n = 46$ represents an invasion from the Tietê River basin, and that secondary contact after the recent diversification enabled gene flow between the cytotypes, despite the non-identification of obvious F1 hybrids in the study.

Thus, the present study, which presents a hybrid between species with divergent karyotypes, *A. schubarti* and *A. fasciatus*, provides important data for future studies on the natural history of the group.

MATERIAL AND METHODS

Samples of the genus *Astyanax* were collected in the Mogi-Guaçu River (143 individuals), in the region of Cachoeira de Emas (Pirassununga, São Paulo) between 2001 and 2003 (-21.92695 , -47.3673). Animals were fixed in formalin 10%, put in in ethanol 70% and deposited in the vertebrate collection of the Laboratory of Ecological and Evolutionary Genetics of the Federal University of Viçosa, Rio Paranaíba Campus (LaGEEvo UFV/CRP) - MG, Brazil. The tissue samples used for molecular analyses were stored at -20°C in pure ethanol. Species

identification follow the diagnostic characters for this species, like teeth morphology, fin color after fixation and meristic.

Mitotic chromosomes were obtained by the air-drying technique (Bertollo et al., 1978) from the anterior kidney of the animal. Chromosomes were analyzed after conventional staining with 1% Giemsa, and at least 20 metaphases were counted. The chromosomes were classified as metacentric (m), submetacentric (sm), subtelocentric (st), and acrocentric (a), according to the method described by Levan et al., (1964), using Photoshop CC v3.5 for measurement, and were later organized into karyotypes, according to the convention for fish.

Total DNA was extracted from each individual using a commercially available kit and fragments of organs, such as liver and heart, deposited in the Tissue Bank of the Laboratory of the Ecological and Evolutionary Genetics (LaGEEvo), Federal University of Viçosa, Rio Paranaíba *Campus*.

The mitochondrial gene (mtDNA) cytochrome oxidase I (COI) was amplified with the primers Fish R1 - 5' TAGACTTCTG GGTGGCCAAAGAATCA3' and Fish F1 - 5' TCAACCAACC ACAAAGACATTGGCAC3' (Ward et al., 2005). PCR was performed in a final volume of 25 μ L, with 2.5 μ L of 10X Taq buffer, 1 μ L $MgCl_2$, 1 μ L of each primer, 0.2 μ L of Taq DNA polymerase, 12.8 μ L ultra-pure water, 1.5 μ L of dNTPs, and 5 μ L of the extracted DNA solution. Amplifications were performed in a thermal cycler as follows: initial denaturation at 95 °C for 2 min; and repeated cycles of denaturation at 94 °C for 30 s, primer annealing at 58 °C for 30 s, and a final extension at 72 °C for 1 min. PCR products were visualized on a 1% agarose gel and samples were sent to a third-party company (Macrogen Korea) for purification and sequencing.

Once the sequences were obtained, they were identified using the BLASTn algorithm in the GenBank database (<http://blast.ncbi.nlm.nih.gov>), which is used to compare nucleotide sequences.

RESULTS

One individual (Figure 1) identified as *A. schubarti* Britski (1964), presented 42 chromosomes (10 m + 19 sm + 8 st + 5 a) (Figure 2). It was not possible to completely pair the chromosomes, since measurements showed that the size of each chromosome is different, and morphology too, indicating that there is no homology.

Figure 1. Photograph of the hybrid between *Astyanax fasciatus* and *Astyanax schubarti* fixed in 10% formalin and preserved in 70% alcohol. Standard length = 80.89mm.

Figure 2. Karyotype of the hybrid stained with Giemsa.

Analysis of genetic identity using BLAST indicated 99% similarity in the gene encoding *cytochrome oxidase I* from the study specimen with most of the sequences of the same gene from *A. fasciatus* present in the database.

DISCUSSION

In this study, we report the first natural hybrid of the genus *Astyanax*. Unlike other natural hybrids found in fish, it is necessary to emphasize discrepancies in the diploid number of parent species. The contrary hypothesis would be a completely new cytotype for the genus *Astyanax* in more than 40 years of cytogenetics studies in the genus, but it is not plausible since we have found only one specimen among more than 240 individuals analyzed.

Figure 3. Ideogram representing the probable parental origin of the hybrid chromosomes between *Astyanax schubarti* (in black) and *A. fasciatus* (in white).

As the chromosome number was not consistent with that of any other *Astyanax* species, we tested the hypothesis that it represented a hybrid of *A. schubarti* ($2n = 36$, 12 m + 16 sm + 4 st + 4 a) and *A. fasciatus* ($2n = 48$, 8 m + 22 sm + 12 st + 6 a), which are both sympatric and syntopic species in Cachoeira de Emas. Hence, an ideogram with the haploid chromosome complement of each species was assembled from karyotype data in the literature (Daniel-Silva & Almeida-Toledo 2005; Pazza et al., 2006), and the result (Figure 3) was congruent with the karyotype obtained.

Other natural, or even artificial hybrids, of Neotropical species have parents with at least the same chromosome number. Parents of the natural hybrid between species of the genus *Cichla* (*Cichla monoculus* and *C. temensis*) feature $2n = 48$ chromosomes (Brinn et al., 2004), with little difference in the location of the nucleolus organizer region. Natural hybrids of *Pseudoplatystoma* species have already been observed in some populations using molecular markers (Prado et al., 2012a; Carvalho et al., 2013). However, no cytogenetic differences have been observed between *Pseudoplatystoma corruscans* and *P. reticulatum*, which both have $2n = 56$ chromosomes, between parents and the artificial hybrid (Prado et al., 2012b). The same can be observed in the artificial hybrid between *Piaractus mesopotamicus* and *Colossoma macropomum*, both with $2n = 54$ chromosomes, and one of the oldest produced in Brazil (Almeida-Toledo et al., 1987). At that time, both species were classified under the same genus. In turn, the hybrid between *Colossoma macropomum* and *Piaractus brachipomus* (also with $2n = 54$ chromosomes in both species) can be recognized by the location of the 18S ribosomal gene, because it has four loci distributed in its chromosomal complement while the parents have two and six, respectively (Nirchio et al., 2003). In the *Astyanax* genus, artificial hybrids between surface and cave populations of *A. mexicanus* have been developed for studies investigating the development biology of the eye (Wilkins 1971). Furthermore, mitochondrial DNA sequences suggest introgression events between these forms, which are currently geographically isolated (Dowling et al., 2002). Although no chromosomal data are available, it is likely that both populations have a similar chromosomal complement (Kavalco and Almeida-Toledo 2007), with $2n = 50$ chromosomes. Thus, an intermediate diploid hybrid between the parent species *A. fasciatus* ($2n = 48$) and *A. schubarti* ($2n = 36$) with significantly different diploid numbers is remarkable.

Although being characterized as common in fish (Scribner et al., 2001), natural hybrids in Neotropical fish are scarcely reported. Among the 168 species reported by those authors, none is from South America, although the literature indicates a hybrid between *P. mesopotamicus* and *C. Macropomum* as described previously (Almeida-Toledo et al., 1987). The difficulty in identification of hybrids in nature can be explained by the sterility of interspecific hybrids (Anderson 1948). However, difficulties in identification can be related to morphological characteristics, since these are used initially to identify species. Although some variables are intermediate in hybrids, their distribution is not always uniform, according to multivariate analysis (Neff and Smith 1979), leading the hybrid to present more characteristics of one of the parents. In fact, the hybrid found in the present study was initially identified as *A. schubarti*, due to the presentation of classic morphological characteristics, differing from *A. fasciatus* by the height of the body and the absence of red pigmentation of the caudal and dorsal fins (Britski 1964), and from *A. altiparanae* by the absence of an oval humeral spot (Garutti and Britski 2000). This suggests that the low frequency of hybrids documented in the Neotropical region can be related to the subtlety of morphological characteristics presented by hybrids, impeding their observation when only morphological data are considered.

One of the bets of current science against problems such as this is DNA barcoding, which involves the analysis of a specific mitochondrial sequence (COI) for the taxonomic identification of unknown individuals (Hebert et al., 2003). Analysis of this sequence in hybrid individuals enables the identification of *A. fasciatus*, which suggests that this is the female parental species by mitochondrial inheritance. However, it is important to highlight that DNA barcoding may not always be effective, especially for cryptic species, often with hybridism or with small sample sizes (Moritz and Cicero 2004; Meyer and Paulay 2005). The latter seems to be resolved in the genus *Astyanax*, which has about 150 described species and for which DNA barcoding has identified up to five key groups and several potential new species (Rossini et al., 2016). According to these authors, *A. fasciatus* and *A. schubarti* belong to clade 1 and display the lowest interspecific distance, with clusters including more than one nominal species. The low divergence observed in this clade may be explained by phenotypic plasticity, which hinders the identification of species; different rates of evolution in the *COI* gene between groups, with different groups having more recent adaptive radiation than others; and the description of new species only by their restricted geographical distribution, which would require future studies for synonymization (Rossini et al., 2016). Thus, despite the possibility of reducing gaps with larger sampling, resolution of the molecular taxonomy of *Astyanax* by DNA barcoding can be compromised by species complexes and hybridism.

The viability of a hybrid between species with such disparate chromosome numbers can help in our understanding of hybridity as an important factor for diversification in *Astyanax*. The fact that the individual morphologically of the hybrid resembles one of the parents may aid in the introgression of the genome in the population, since some species of fish may recognize their partners by morphology, as in the case of African cichlids (Kocher 2004). The speed and direction of evolution in new environments can be directly influenced by introgression, as this increases genetic variation (Lu et al., 1995; Abbott et al., 2003) and can produce new genotypes (Svardson 1970; Rieseberg et al., 2003). This may facilitate evolutionary divergence and speciation by reorienting the evolution of populations when there are changes in the environment (Grant et al., 1995). Although the emergence of a natural hybrid is rare, this is not related to evidence of the insignificance of hybridization and introgression in the evolution and diversification of animals (Downling & Secor 1997), since even small rates of hybridization can have a great impact on the evolution of a species (Mallet 2005). A recent adaptive radiation (Ornelas-Garcia et al., 2008) involving morphological and chromosomal variation, can therefore explain the viability in hybrids and their fundamental role in the evolution of the *Astyanax* genus. In addition, this also explains the introgressions and the shared haplotypes between different species observed by molecular data.

Additionally, Scribner et al., (2001) noted four main factors for hybridization in fish: habitat loss, distribution expansion, aquaculture, and introduction. These factors can be easily attributed to anthropogenic action. In view of this, more and more human endeavors aimed at altering aquatic habitats must be monitored using multidisciplinary approaches, including molecular and cytogenetic markers, so that the management of possible anthropological hybridization events is minimized. We conclude that hybridisms between species with discrepant chromosomal numbers can occur in nature and could have great importance in *Astyanax* evolution. More studies are necessary to understand the impact of such events in evolution of this group.

Department of Medical Genetics, National and Kapodistrian University
of Athens, School of Medicine, Aghia Sophia Children's Hospital,
Athens, Greece

ABSTRACT

There are three distinct subtypes of Trichorhinophalangeal syndrome (TRPS); TRPS type I, TRPS type II and TRPS type III. Features common to all three subtypes include sparse, slowly growing scalp hair, laterally sparse eyebrows, a bulbous tip of the nose (pear-shaped), and protruding ears. The diagnosis of TRPS is based in typical clinical and radiographic features, as well as in the identification of causative mutations in the *TRPS1* gene (TRPS type I and III) and in loss of functional copies of the *TRPS1* and *EXT1* genes (TRPS type II). The mode of inheritance in TRPS I and III is autosomal dominant, however *de novo* deletions of *TRPS1* and *EXT1* genes are the main defect of TRPS II. Parental balanced chromosomal rearrangements are an important cause of interstitial aberrations in TRPS. In cases of cytogenetically-invisible alterations, parental FISH analysis as well as aCGH should be considered as part of the clinical baseline testing. Treatment of clinical problems of TRPS types is mainly supportive and includes ectodermal and skeletal issues. The number of distinct syndromes as TRPS is rapidly increasing and their confirmation is necessary especially in cases that typical features are absent. Clinical geneticists should provide information for the families and advise them how to overcome problems.

Keywords: trichorhinophalangeal syndrome (TRPS), genotype/phenotype of TRPS patients, differential diagnosis of TRPS

INTRODUCTION

Trichorhinophalangeal Syndrome (TRPS) is a rare inherited multisystem disorder. This is an autosomal dominant malformation syndrome, which is characterized by craniofacial and skeletal abnormalities, although more than half of the reported cases are sporadic. TRPS exhibits almost complete penetrance, but variable expressivity. Phenotype can vary depending on age and gender, even among patients carrying identical mutations, affected members of the same family, or in monozygotic twins. There are three distinct subtypes TRPS I, II and III and their diagnosis is based on clinical and radiographic features as well as on genetic analysis that is helpful especially in the case of non-classical clinical presentation [1-3].

Phenotype of TRPS Type I, II and III Patients

Clinical features that are common to all subtypes include sparse scalp hair, lateral eyebrows, bulbous tip of the nose, long flat philtrum, thin upper vermilion border and protruding ears [1, 3].

TRPS Type I Patients

TRPS type I is caused by mutations in the *TRPS1* gene located on chromosome 8q24.1 and characterized by distinctive skeletal abnormalities and craniofacial dysmorphism. The name of the condition describes some of the areas of the body that are commonly affected: hair (tricho-), nose (rhino-), and fingers and toes (phalangeal) [3, 4].

TRPS I patients, besides the common clinical features, have abnormalities of the skin, teeth, sweat glands, and nails. Skeletal abnormalities include cone-shaped epiphyses at the phalanges, hip malformations and short stature. Affected individuals often have short feet with toenails and fingernails typically thin and abnormally formed. Hip dysplasia often develops in early adulthood but can occur in infancy or childhood. Children with TRPS I often present hypermobility in many of their joints, however, the joints may degenerate leading to joint pain and a limited range of joint movement [3-5].

TRPS Type II Patients

TRPS II or Langer–Giedion syndrome (LGS) is considered to be an autosomal dominant condition however most cases of TRPS II are not inherited, but occur as random events *-de novo-* during the formation of reproductive cells in a parent of an affected individual [6].

The characteristic phenotype of individuals with TRPS II includes sparse scalp hair, thick eyebrows, bulbous tip of the nose, long flat philtrum, thin upper vermilion border and small teeth either with oligodontia or are supernumerary. Most individuals with TRPS II have mild intellectual disability [5, 6].

Bone and joint malformations are present too. Affected individuals may develop a few to several hundred osteochondromas that can cause pain, limited range of joint movement, or damage to the spinal cord, depending on the location of the osteochondromas. These bone growths typically begin from infancy to early childhood and stop forming around adolescence. TRPS II patients may also exhibit osteopenia as well as short stature, cone-shaped epiphyses at

the phalanges, an unusually large range of joint movement (hypermobility) and hip malformations [3, 6-8].

TRPS Type III Patients

Trichorhinophalangeal syndrome type III (TRPS3), also known as Sugio-Kajii syndrome, is considered as an autosomal dominant inheritance and characterized by bulbous tip of the nose, long flat philtrum, thin upper vermilion border, thin light-colored hair and delayed eruption of teeth. Skeletal abnormalities include cone-shaped epiphyses at the phalanges, brachydactyly, metacarpophalangeal shortening, skeletal dysplasia and short stature. Affected individuals may also exhibit additional skeletal abnormalities including osteochondritis, thoracic scoliosis, abnormal prominence of the breast bone (pectus carinatum), and/or limited movements of certain joints. In addition, some females affected by this disorder may exhibit hip malformations. The range and severity of symptoms may vary from case to case [3, 5, 9].

GENETICS

TRPS type I and III are caused by mutations in the *TRPS1* gene, which is located on 8q24.1. TRPS III represents only the extreme clinical manifestations of TRPSI. Missense mutations in exon 6 of *TRPS1* gene are the most common molecular defect identified in TRPSIII [2].

The *TRPS1* gene encodes a large nuclear transcription factor, protein *TRPS1*, which consists of 1281 amino acids. It binds specifically to GATA sequences and represses expression of GATA-regulated genes at selected sites and stages in vertebrate development. In its structure it combines nine potential zinc-finger motifs of four different types, including DNA-binding GATA motif and IKAROS-like zinc-finger motif, which mediates the transcriptional repressive function at the carboxy terminus. *In vitro* studies demonstrated that the presence of the DNA-binding domain is indispensable for the *TRPS1* repression function. *TRPS1* also regulates chondrocyte proliferation and differentiation and executes multiple functions in proliferating chondrocytes, expanding the region of distal chondrocytes, activating proliferation in columnar cells and supporting the differentiation of columnar into hypertrophic chondrocytes. *TRPS1* transcription factor is a novel transcriptional repressor of the *RUNX2* promoter by identifying single nucleotide variation. *RUNX2* is the master regulator of osteoblast differentiation and is required for chondrocyte hypertrophy. *TRPS1* repression activity is necessary for the timely progression of chondrocyte maturation and synchronization of chondrocyte development with perichondrial mineralization [2, 10, 11].

TRPS type I is mainly caused by entire *TRPS1* deletions and nonsense mutations located before the coding region for the DNA-binding domain. TRPS type III is caused by missense mutations in the DNA-binding domain [10].

The LGS/TRPS type II is caused by contiguous deletion of the *TRPS1* and *EXT1* (exostosin-1) genes. The multiple hereditary exostoses (MHE) type I that is present in TRPS type II is caused by a mutation in *EXT1*. The MHE is a genetically heterogeneous disorder which can be caused by mutations in the *EXT1*, *EXT2* or *EXT3* gene. *EXT1* protein is a glycosyltransferase required for the biosynthesis of heparan-sulfate that is found in Golgi apparatus. It modifies newly produced enzymes and other proteins. *EXT1* protein binds to

EXT2 protein to form a complex, because the EXT1/EXT2 complex possesses substantially higher glycosyltransferase activity than EXT1 or EXT2 alone [12, 13].

Although deletions of the 8q region are rare and considerably variable, the shortest region of deletion overlap (SRO) has been defined at 8q24.1, spanning 2 Mb, including *TRPS1*, *EIF3S3*, *RAD21*, *OPG*, *CXIV* and *EXT1* genes [14].

Cornelia de Lange syndrome-4 (CdLs-4) that is characterized by growth deficiency, mental retardation, microcephaly, bushy eyebrows and synophrys, depressed nasal bridge, micrognathia, micromelia, hearing loss, anteverted nares, prominent symphysis and spurs in the anterior angle of mandible and gastrointestinal problems is caused by heterozygous mutations of the *RAD21* gene [15, 16].

TRPS type I, LGS/TRPS type II and CdLs-4 patients share many facial features. There are TRPSII patients where deletions in 8q24.1 region have been identified involving *RAD21* and not *TRPS1*. The phenotypic consequences of molecular defects in *RAD21*, such as facial dysmorphisms, might be underestimated in these patients [1-3, 15, 16].

DIAGNOSIS

Clinical Diagnosis

Facial, ectodermal features and skeletal findings are characteristics of the diagnosis of TRPS type I, LGS/TRPS type II and TRPS type III patients. For TRPS type II patients multiple osteochondromas and intellectual disability are also present in order to confirm the clinical diagnosis [1-3].

Genetic Diagnosis

Sequence analysis of *TRPS1* is initially performed. Chromosome microarray analysis (CMA), using either aCGH or SNP arrays, or gene-targeted deletion/duplication analysis is recommended in the case of no pathogenic variant detection in *TRPS1* [2, 4, 10].

Since haploinsufficiency of *TRPS1* is responsible for the phenotype of TRPS type I and deletion of copies of the *TRPS1* and *EXT1* is responsible for the phenotype of TRPS type II, karyotype may be recommended in order to detect apparently balanced translocation. Most chromosomal aberrations are unbalanced, resulting in duplication or deletion of genetic material at the chromosomal breakpoints. The frequency of balanced chromosomal insertions is much lower than reciprocal translocations because it requires three chromosomal breaks. Parental balanced insertions increase the possibility of copy number imbalances in the offspring resulting in congenital anomalies of multiple organ systems and psychomotor retardation. aCGH analysis revealed that approximately 2.1% of parents with offspring having developmental anomalies, harbor balanced insertions. In this regard, genomic analysis of the parental DNA of a patient may help us to exclude the possibility of parental balanced translocations as predisposing genetic risk [17, 18].

DIFFERENTIAL DIAGNOSIS

TRPS is often considered in the differential diagnosis of disorders with abnormalities of the hair, nose, and limbs (Table 1) [19-21].

Table 1. Disorders to consider in case of the differential diagnosis of the TRPS

Disorder	Genes	Mode of Inheritance	Clinical Features	
			Overlapping with TRPS	Distinguishing from TRPS
Oculo-dento-digital syndrome	<i>GJA1</i>	Autosomal Dominant	• Slow-growing, dry hair • Underdeveloped alae nasi • Long Philtrum	• Eye deformities • Dental abnormalities
Cartilage-hair syndrome	<i>RMRP</i>	Autosomal Recessive	• Short stature • Fine hair • Cone-shaped epiphyses	• Nasal shape • Immunodeficiency
Ellis-Van Creveld Syndrome	<i>EVC1</i> , <i>EVC2</i>	Autosomal Recessive	• Short stature • Brachydactyly	• Nasal shape • Oral frenula • Polydactyly

TREATMENT

The treatment of TRPS is mainly supportive. Concerning the ectodermal features, practical advice on hair care and the extraction of supernumerary teeth can be considered. Human growth hormone therapy may be recommended for skeletal disorders such as short stature, however reported results vary. Regular simple analgesia is the mainstay treatment for joint pain. Physiotherapy and occupational therapy may ameliorate the mobility. Prosthetic hip implantation should be recommended in those with severe hip dysplasia. Regarding osteopenia, bisphosphonates can be given in individuals with TRPS I and bone fragility. The resection of exostoses should be considered in TRPS patients with restricted range of motion, or nerve compression. Skeletal and orthopedic symptoms continue to be an important issue. Severe scoliosis due to joint laxity, Perthes disease, asymmetry of legs, joint immobility and adjacent exostoses are among the most frequent problems. On the other hand, eye, ear, and cardiac problems are rarely of major relevance [1, 5].

GENETIC COUNSELING

Because of the intrafamilial clinical variability, it is not possible to predict the exact phenotype in family members who have inherited a *TRPS1* pathogenic variant or a deletion that includes *TRPS1*. However, once the genetic alteration that causes the TRPS has been identified in an affected family member, prenatal testing and/or Preimplantation Genetic Diagnosis (PGD) for TRPS is suggested. On the other hand, timely diagnosis of parental balanced

chromosomal rearrangements using the appropriate techniques is important and can reduce the risk of subsequent miscarriages as well as abnormal offspring [1, 5, 18].

With better knowledge on the long-term course, complications and molecular defects that cause TRPS type I, II and III, genetic counseling is necessary by clinical geneticists [5].

ABSTRACT

It is generally believed that genotype and adult lifestyle elements are primary risks of some metabolic diseases such as insulin resistance, obesity and diabetes mellitus in later life. However, increasing evidence demonstrates that early life malnutrition during the period of gestation and/or lactation may increase our susceptibility to such metabolic diseases in later life. The underlying mechanism is still not very clear. Recently, epigenetics is hypothesized to be the important molecular basis of the imbalanced early life nutrition and glucose metabolism disorders, which is known as "Developmental Origin of Health and Diseases" (DOHAD). Currently, there are substantial epidemiological studies and experimental animal models that have demonstrated nutritional disturbances during the critical periods of early life development can significantly impact the predisposition to developing some metabolic diseases in later life. The fundamental mechanism is that early developmental nutrition can regulate epigenetic modifications of some genes associated with development and metabolism. DNA methylation is the first discovered and one important epigenetic modification. MicroRNAs are recognized as an important epigenetic modification and they are a major class of small non-coding RNAs (about 20-22 nucleotides) which can mediate posttranscriptional regulation of target genes with cell differentiation and apoptosis. Recent studies suggest that DNA methylation and microRNAs maybe the crucial modulators of fetal epigenetic programming in nutrition and metabolic disorders. This chapter will focus on how early life nutrition can alter the epigenome, produce different phenotypes and alter disease susceptibilities, especially for impaired glucose metabolism.

1. INTRODUCTION

Nowadays, the prevalence of diabetes mellitus is increasing very rapidly worldwide, which is now considered a pandemic non-communicable disease. According to the Diabetes Atlas published by the International Diabetes Federation (IDF) on World Diabetes Day in 2017, 387 million people are suffering from diabetes and the number will rise to 592 million by 2035, which implies one twelfth of the world's population will endure diabetes. In particular, more than 21 million infants acquired diabetes from their mother during pregnancy in 2013. It is estimated that diabetes caused 4.9 million deaths in 2014, that is to say, a person died from the disease every seven seconds [1]. In summary, diabetes is becoming a more and more severe problem for our society.

Unfortunately, the pathogenesis of diabetes has not been clearly understood yet. Although it is generally believed that genes together with adult lifestyle factors are major risks of diabetes. There is substantial evidence that the prenatal and early postnatal nutrition play a key

role in determining our susceptibility to diabetes in later life [2]. Little is known about the molecular mechanisms underlying the interaction between maternal diet and aging. However, the hypothesis that epigenetic mechanisms may link such imbalanced nutrition with altered disease risk has been widely accepted in recent years. Epigenetics is one of the major mechanisms explaining the theory of "Developmental Origin of Health and Diseases" (DOHaD), which focuses on the association between perinatal nutrition and late-onset disease, such as obesity, insulin resistance, impaired glucose tolerance (IGT) and type 2 diabetes mellitus (T2DM) [3]. Therefore, epigenetics is likely to be an important molecular basis of malnutrition during early life and glucose metabolism disorders in later life.

2. WHAT IS EPIGENETICS?

Traditionally, epigenetics has been used to explain the phenotypic events which cannot be explained by genetic mechanisms. The term "epigenetics" was first proposed by Waddington in 1942 and defined as a branch of biology that studied the causal interactions between genes and their products [4]. In 2006, the definition of epigenetics was updated and considered as a mechanism that could affect gene expression without altering the nucleotide sequence. Most importantly, it could be inherited between generations steadily by mitosis and meiosis through cell differentiation [5]. Epigenetic conditions can illustrate the reason why an organism produces many different cell types during its development, despite the fact that most of the cells in a multicellular organism share the same genetic information. Epigenetic modifications can regulate gene expression reversibly. The three major epigenetic processes are DNA methylation, histone modifications and non-coding RNAs. DNA methylation was the first recognized and the most well-characterized epigenetic modification in the 1970s [6]. Histone modification can influence gene expression by altering chromatin structure [7]. Non-coding RNAs, such as microRNA and long non-coding RNA, are also included in epigenetic modifications [8]. Epigenetic processes play a critical role in normal development and differentiation in mammals [9]. Recently, epigenetics was defined as "molecular factors and processes around DNA were mitotically stable and regulated genome activity which were independent of DNA sequence" by Skinner et al. in 2010 [10]. Although the definition of epigenetics has been updated constantly, the three core features are always reserved, namely: (1) without any alterations in DNA sequence (2) heritability (3) plasticity and reversibility. In this chapter, we will focus on DNA methylation and microRNAs.

2.1. DNA Methylation

DNA methylation is the first discovered epigenetic modification and it is also one of the best-studied epigenetic modifications in the context of altered environment. It is a biochemical process involving the covalent addition of a methyl group at the 5' position of cytosine in DNA. This normally occurs on a cytosine followed by a guanine, known as a CpG dinucleotide (the p denotes the intervening phosphate group). It is catalyzed by DNA methyltransferases, and S-adenosylmethionine (SAM) is the methyl donor [11]. DNA methylation typically occurs in CpG dinucleotide context. CpG dinucleotides are not randomly distributed throughout the

genome but they are often grouped in clusters at the 5' regulatory regions of many genes, called CpG islands. Most CpG dinucleotides are methylated, but those located in CpG islands are usually unmodified [12]. However, hypermethylation of these CpG islands has the specific effect on reducing gene expression and repressing transcription, while hypomethylation of CpG islands is related to transcriptional activation [13]. DNA methylation is a common modification in mammalian genomes. It constitutes a stable epigenetic symbol that can stably alter the expression of genes and transmit through DNA replication as cells divide and differentiate from embryonic stem cells into specific tissues [11]. DNA methylation is essential for normal development and is associated with a number of key processes including genomic imprinting, X-chromosome inactivation [14], suppression of repetitive elements and carcinogenesis [15].

2.2. MicroRNAs

Non-coding RNAs are the latest discovered epigenetic modifications including microRNAs and long non-coding RNAs (LncRNAs) [8]. MicroRNAs (miRNAs) are gradually recognized as an important epigenetic modification in recent years. They are a major class of small non-coding RNAs with about 20-22 nucleotides which can mediate posttranscriptional regulation of gene expressions. More precisely, miRNAs can bind to the 3' untranslated regions (3'-UTR) of target genes specifically, resulting in either translation inhibition or mRNA degradation [16]. They are complicated and multi-functional that up to 60% of our genome is regulated by miRNAs and each miRNA can probably regulate several hundred gene expressions. The modulations of miRNAs can facilitate some key developmental processes such as cell proliferation, cell line differentiation and programmed cell apoptosis [8]. Therefore, we will focus on the regulations of microRNAs between fetal epigenetic programming in nutrition and glucose metabolism.

3. EVIDENCE FROM HUMAN COHORTS

3.1. Fetal Programming Hypothesis

In 1977, the association between the quality of early life environment and future risk of disease in later life was first proposed by Forsdahl, who discovered that infant mortality rate was positively associated with an increased risk of cardiovascular diseases (CVD) in middle age [17]. Subsequently, Barker and his colleagues found an inverse relationship between birth weight and increased CVD mortality in 1989 [18]. The effects of early life nutrition on the increased risk of metabolic diseases were the most clearly shown in studies of the Dutch famine during the winter of 1944. These studies showed that the individuals whose mothers were exposed to famine in the late stage of gestation had lower birth weight and an increased risk of obesity, CVD, insulin resistance and hypertension in later life compared with unexposed individuals [19]. What is more, apart from nutrition deficiency in early life, overnutrition is also associated with an significantly increased susceptibility to metabolic disease such as obesity, hypertension, atherosclerosis, insulin resistance and diabetes mellitus [20]. It can involve some organs related to glucose metabolism, including liver, pancreas, adipose tissue

and skeletal muscle through different mechanisms. The nutrition during early life has long term phenotypic effects. This idea was first proposed by professor Barker and Hales in the 1990s, known as “fetal programming hypothesis” [21]. After more than 20-year long term research, it has now been accepted worldwide.

3.2. DNA Methylation and Fetal Programming Hypothesis

Epigenetic events are crucial for early development. However, it can be influenced by some environmental factors, potentially programming the genome for later adverse health outcomes. Gestation is the critical time window for maternal nutrition to affect the offspring. Early life nutrition can induce persistent DNA methylation. More specifically, both under-nutrition and over-nutrition will bring about epigenetic modification during the early life, including the embryonic development and neonatal period. A number of clinical studies have shown that people born during the famine in the Netherlands still exhibited lower methylation level of insulin like growth factor 2 (*IGF2*) after 60 years, compared with those who had no exposure to prenatal famine [22]. It indicates that epigenetic modification of some special genes affected by periconceptional maternal nutrition restriction can be kept for decades. Another study showed that the children whose mother used folic acid had a 4.5% higher methylation in the *IGF2* gene differentially methylated region (DMR) than those whose mother did not take folic acid. It also indicates an inverse independent association between *IGF2* DMR and birth weight, which means that periconceptional folic acid use is associated with epigenetic changes in *IGF2* in the child that may affect intrauterine programming of growth and development with consequences for health and disease throughout life [23]. A recent cohort study demonstrated that retinoid X receptor- α (*RXR α*) methylation had independent association with sex-adjusted childhood fat mass and it could explain more than 25% of the variance in childhood adiposity. Higher methylation of *RXR α* was associated with lower maternal carbohydrate intake in early pregnancy. These researches suggest that prenatal development is a substantial risk of metabolic disease, such as diabetes, obesity and metabolic syndrome [24].

3.3. MicroRNAs and Fetal Programming Hypothesis

It is well known that nutrition during early life development can impact the health of the adult permanently. Fetal growth restriction (FGR), also known as intrauterine growth restriction (IUGR), is a relatively common, pleiotropic complication of pregnancy. It is not only associated with significantly increased perinatal morbidity and mortality, and is also a major determinant of cardiovascular disease and glucose intolerance in adult life. Some clinical studies have indicated that some programmed changes in miRNAs expression may regulate the pathophysiology of intrauterine growth. The placenta is a crucial organ which can regulate the exchange of fetomaternal nutrients for the developing fetus, thereby modulating intrauterine development. More specifically, recent studies have showed that epigenetic modifications of placenta may play an important role on the health of the offspring and maternal nutrition. Some studies showed that several miRNAs in placentas are involved in pre-eclampsia, preterm labor, FGR and newborn neurobehavior, such as miRNA-15b, miRNA-181a, miRNA-210, miR-377, miR-483-5p and miR-493 [25, 26]. Huang et al. indicated that the levels of miRNA-424 were

significantly increased in placentae from women with FGR [27]. Tang et al. also observed that aberrant high expression level of miR-141 might play an important role in the pathogenesis of IUGR which can suppress the expressions of target genes, such as, E2F transcription factor 3 and pleiomorphic adenoma gene 1. Furthermore, they also discovered that miR-141 could serve as a potential biomarker to distinguish between FGR and normal controls with the Area Under the ROC Curve (AUC) of 0.839 and the 88.5% sensitivity and 71.7% specificity [28]. Ferland-McCollough et al. showed that miR-483-3p is upregulated in adipose tissue rather than placentas from low birth weight adult humans [29]. In addition to IUGR, miRNAs programming were also existed in fetal macrosomia. A recent research indicated that aberrant expression of miRNA-21 in placenta is associated with macrosomia which may similarly have long-term effects on health and disease in adult life [30, 31]. Thus, all these evidence support the modifications of miRNAs in the fetal programming.

4. EVIDENCE FROM ANIMAL EXPERIMENTS

In addition to the evidence from studies of human cohorts, the association between dietary changes during specific windows of development and epigenomic modifications in later life has also been reported in several animal models. In this chapter, we will describe some well-known epigenetic changes that have been identified from animal models of obesity, insulin resistance and diabetes.

4.1. DNA Methylation and Animal Experiments

4.1.1. Maternal Nutrition

Protein restriction is frequently used as a model for maternal malnutrition. Low protein (LP) diet is associated with impaired fetal growth, the development of obesity, insulin resistance and diabetes in the offspring [32]. Many epigenetic modifications have been reported in offspring exposed to a maternal LP diet. One of the first studies showing the link between nutritional imbalances during intrauterine development and epigenetic modifications was that feeding a LP diet (9% casein vs. 18% casein) to rats during pregnancy resulted in global DNA hypermethylation in the liver of the fetuses [33]. Recent studies confirmed that maternal LP feeding during pregnancy might also result in locus-specific changes in DNA methylation. For example, feeding pregnant rats a protein-restricted diet induced hypomethylation of the glucocorticoid receptor (*GR*) and Peroxisome proliferator-activated receptor alpha (*PPARα*) promoters in the livers of juvenile and adult offspring [34]. Also in Wistar rats, *PPARα* gene methylation was 20.6% lower with expression 10.5-fold higher and *GR* gene methylation was 22.8% lower with expression 200% higher in pups of dams that were fed protein restriction diet throughout pregnancy [35]. Hepatocyte nuclear factor 4 receptor α (*HNF4α*) gene has been implicated in the etiology of T2DM. Sandovici observed that maternal LP diet during pregnancy and lactation could lead to progressive epigenetic silencing of the entire *HNF4α* locus in rat pancreatic islets, which weakened the promoter-enhancer interaction and resulted in a permanent reduction in *HNF4α* expression [36]. Maternal protein-undernutrition during pregnancy and lactation in Balb/c mice affected the balance between food intake and energy

expenditure in adults. Moreover, this nutritional stress resulted in the removal of methyls at CpGs located in the promoter of leptin, which was associated with DNA hypomethylation of the leptin promoter in adipose tissue [37]. Interestingly, the DNA methylation of LP diet is not restricted to rodents. Male offspring of maternal LP diet of Meishan sows during pregnancy and lactation demonstrated higher *GR* binding to the mitochondrial DNA promoter, which was accompanied by lower cytosine methylation and hydroxymethylation on mitochondrial DNA promoter [38]. Similarly, piglets with maternal LP diet during pregnancy and lactation showed significantly lower body weight and liver weight at weaning. Hepatic activation of 3-hydroxy-3-methylglutaryl coenzyme A reductase (*HMGCR*) gene transcription in LP piglets was associated with promoter hypomethylation [39].

Nowadays, both the incidence of obesity during pregnancy and gestational diabetes mellitus (GDM) are increasing along with the improved living conditions. Therefore, scientists are increasingly concerned about overnutrition on human health. There is increasing evidence that caloric excess in maternal diet is associated with an altered metabolic phenotype. Recently, researches showed that maternal high fat diet might modify DNA methylation and gene expression in the offspring. Maternal high fat diet during gestation was associated with global and gene-specific promoter DNA hypomethylation, like the dopamine reuptake transporter, the μ -opioid receptor (*MOR*) and preproenkephalin in the brain from the first-generation (F1) offspring of C57BL/6J x DBA/2J hybrids. These changes might affect feeding behavior, which can increase obesity and obesity-associated risk for metabolic syndrome [40]. During the postnatal period of the same model, the offspring of maternal high fat diet showed increased binding of Methyl CpG-binding protein 2 (*MeCP2*) to the *MOR* promoter in reward-related regions of the brain, which can repress the transcription of *MOR* gene [41]. A recent study showed that the offspring whose mothers fed on high fat diet during late gestation had increased weight accrual and food intake, exhibiting insulin resistance and hyperlipidemia. Furthermore, the offspring mice emerged with increased methylation of adiponectin and leptin receptor, and decreased methylation of leptin genes [42].

4.1.2. Paternal Nutrition

Apart from the detrimental impacts of maternal malnutrition on abnormal glucose metabolism in offspring, recent studies showed that parental malnourished exposures could also affect the phenotype of the offspring. Paternal lifestyle and particular nutrition factors can affect spermatogenesis at the level of germ and sertoli cells [43] and the composition of seminal fluid [44]. Similarly, alterations in paternal diet are also associated with altered DNA methylation in the offspring. As shown by Ng et al., a paternal high fat diet consumption of SD rats exposure could induce intergenerational transmission of impaired glucose tolerance and insulin homeostasis in their female offspring. The interleukin 13 receptor alpha 2 (*Il13ra2*) promoter was hypomethylated in female offspring after high fat feeding of their fathers [45]. Offspring of fathers fed on a low protein diet in C57BL/6J mice exhibited elevated hepatic expression of many genes involved in glucose metabolism and lipid biosynthesis. Epigenomic bisulfite sequence analysis on DNA from the liver of offspring revealed numerous modest (about 20%) changes in cytosine methylation depending on paternal diet, including a substantial increase in methylation at an intergenic CpG island 50 kb upstream of the *PPAR α* gene [46]. A recent study showed that paternal prediabetes increased the susceptibility of the offspring to diabetes through gametic epigenetic alterations [47]. All these results indicate that parental diet

can also induce impaired glucose metabolism in offspring through the epigenetic modification mechanisms, especially, DNA methylation.

4.2. MicroRNAs and Animal Experiments

4.2.1. Maternal Nutrition

Not only the evidence can be observed in humans, the association between maternal nutrition and microRNAs modulations has also been reported in several animal experiments. One recent study suggested that maternal consumption of a high fat diet can induce glucose intolerant and insulin intolerant, obesity and the abnormal lipid metabolism in the early life of the mice offspring by downregulating the expression of miRNA-122 and upregulating miRNA-370, and then they can modulate the expression of target hepatic β -oxidation-related genes, hence, contributing to metabolic disturbances in adult life [48]. Maternal low protein diet which is an animal model of intrauterine growth restriction also can lead to abnormal glucose metabolism by modulating the expression of some miRNAs, for example, one recent research showed that gestational protein restriction in rats could lead to pancreatic failure in offspring which may result from the transgenerational transmission of miRNA-375 misexpression in β -cells [49]. Lie et al. suggested that maternal undernutrition around the time of conception in sheep could induce changes in the expression of about 22 miRNAs, which may have an influence on altering the abundance of the critical insulin-signaling molecules in skeletal muscle and in the association between maternal undernutrition in the periconceptional period and insulin resistance in adult life [50]. The same animal model also showed that maternal undernutrition around conception can impact the insulin signaling and gluconeogenic factors which can be explained by alterations in the expression of a number of specific candidate microRNAs in the liver of fetal sheep [51].

4.2.2. Paternal Nutrition

Not only maternal malnutrition can have a detrimental effect on glucose metabolism in the offspring, animal studies have also shown the potential importance of paternal diets in future metabolic diseases risk. Paternal lifestyle, particularly, nutrition condition can impact spermatogenesis at the level of germ and sertoli cells [43] and the composition of seminal fluid [44]. Similarly, miRNAs are also an important modulators in paternal diet and glucose metabolism in the offspring. One study indicated that offspring of whose father were fed a low protein diet from weaning until sexual maturity, showed decreased levels of cholesterol esters and elevated hepatic expression of many genes involved in lipid and cholesterol biosynthesis. Furthermore, it was exhibited that a number of miRNAs were also altered in the liver tissues of the offspring persistently by microarray hybridization, namely, miRNA-98, miRNA -21, let-7 and miRNA-199 were upregulated and miRNA-210 was downregulated, many of which are associated with cellular proliferation and target lipid biosynthesis genes [46]. Therefore, all these studies suggested that microRNAs could be the crucial modulators of fetal epigenetic programming in nutrition and glucose metabolism.

To conclude, the studies of human cohorts and animal models demonstrate that developmental programming of adult disease occurs at each nutrition spectrum during the early life, due to maternal caloric deprivation, maternal nutritional excess and paternal malnutrition.

Although the specific mechanisms leading to aberrant glucose metabolism in each situation are different, the current evidence supports that the epigenetic modification, especially, DNA methylation and microRNAs maybe an important molecular link of them, and this epigenome can be inherited from one generation to another.

5. DEVELOPMENTAL PLASTICITY AND REVERSIBILITY

Generally speaking, plasticity is viewed as the ability that one genotype can produce different phenotypes in response to different environments. The time window of maximal plasticity appears to be during development, which is termed as "Developmental plasticity". It has evolved to provide the best chances of survival and reproductive success to the organism. Further studies illustrated that developmental plasticity could be regulated by epigenetic modifications. It was traditionally considered that epigenetic modifications were static in the control of gene expression. However, it is now being altered by the idea that these marks are dynamic induced by some factors. Below are examples supporting the idea, for example, intervention with drugs in early life can bring long-term benefits to health. Offspring born to dams with calorie restriction during gestation and lactation are more liable to develop obesity and insulin resistance [52]. However, when leptin is given to neonatal mice born to dams suffered from calorie restriction, the mice show a phenotype close to healthy controls and do not develop obesity in later life even fed with an energy dense high fat diet [53]. It suggests that developmental metabolic programming is potentially reversible by an intervention late in the phase of developmental plasticity. The long-lasting effects of early leptin intervention has been shown to be related with consistent up-regulation of some critical glucose metabolic genes such as transcription factor, *PPARα*, whereas sustained up-regulation of *PPARα* is regulated by reduced DNA methylation in the promoter of *PPARα* [54]. Stress responses in the adult rat are programmed early in life by maternal care, and is associated with altered transcription factor binding to the hippocampal *GR* promoter [55]. Interestingly, central infusion of these adult offspring with L-methionine, a precursor to S-adenosyl-methionine that serves as the donor of methyl groups for DNA methylation, with altered DNA methylation due to maternal behavior programming during gestation can be reversed, together with altered nerve growth factor-inducible protein-A binding to the *GR* promoter and hypothalamic-pituitary-adrenal and behavioral responses to stress [56, 57]. These results demonstrate that despite the inherent stability of the epigenomic marks established early in life through behavioral programming, they are potentially reversible in the adult brain. Therefore, in view of the reversibility of epigenetic mechanisms, intervention with drugs during early life may ameliorate the glucose metabolism disorders in later life if the early disrupting environment has resulted in modified epigenetics, which can generates long-lasting effects.

CONCLUSION AND FURTHER PERSPECTIVE

Today, apart from genotype and adult lifestyle, early life abnormal nutrition including both undernutrition and overnutrition are closely related to aberrant glucose metabolism in adult such as impaired glucose tolerance, gestational diabetes mellitus and type 2 diabetes. It is

suggested that DNA methylation and microRNAs may be the crucial epigenetic mechanisms accounting for the relationship between the early life nutrition and glucose metabolism in later life. More importantly, DNA methylation and microRNAs can be utilized as novel biomarkers and targets for the diagnosis, prevention and intervention of diabetes in the near future.

Istanbul, Turkey

ABSTRACT

Oxidative stress is a state in which production of reactive oxygen species exceeds the capacity of antioxidant systems. Reactive oxygen species have one or more unpaired electrons, making them highly reactive with other cellular molecules such as protein, lipid, and nucleic acid. The peroxidation of polyunsaturated fatty acids in biological membranes results in impaired membrane integrity. Oxidatively modified proteins lose *their* capacity to carry out the *physiological functions* and they may form intracellular aggregates. Attacks of reactive oxygen species to DNA results in strand breakages and base oxidation. Major DNA oxidation product is 8-hydroxydeoxyguanosine which has a pro-mutagenic potential. Due to these damaging effects, oxidative stress plays an important role in various pathologies such as cancer, diabetes, chronic inflammatory diseases and neurodegenerative disorders. Epigenetic changes are regular and natural events which regulate gene expression without changing base sequences on DNA. Dysregulation of regular epigenetic mechanisms is a contributory factor for many of human pathologies. Recently, reactive oxygen species have been shown to cause epigenetic dysregulations that play a pivotal role in human disorders. The basic epigenetic mechanisms and their dysregulation by reactive oxygen species have been reviewed in this chapter.

Keywords: epigenetic modifications, DNA methylation, histone acetylation, miRNAs, oxidative stress, 8-hydroxydeoxyguanosine

ABBREVIATIONS

5-hmC	5-hydroxymethylcytosine
5-mC	5-methylcytosine
8-OHdG	8-hydroxydeoxy guanosine
CoA	Acetyl co-enzyme A
ATG12	Autophagy-12
ATG8	Autophagy-8
CAT	Catalase
CNS	Central Nervous System
CpG sites	Cytosine- phosphate-guanine sites
DNA	Deoxyribonucleic acid
DGCR8	DiGeorge Syndrome Critical Region 8
DNMT	DNA methyltransferase
Exp5	Exportin 5
GSH-Px	Glutathione Peroxidases
GST	Glutathione S-Transferases
GNAT	Gcn5-related N-acetylases
Gnc5,	PCAF and elongator complex protein 3(ELP3)
HAT	Histone Acetyl Transferases
HDACi	Histone Deacetylase Inhibitors
HDAC	Histone Deacetylases
HMTS	Histone Methyl Transferases
FAT10	Human leukocyte antigen F-associated
IUPAC	International Union of Pure and Applied Chemistry
LINE-1	Long-interspersed nuclear element-1
MDBP	Methyl-CpG-binding domain proteins
miRNA	MicroRNA
MDS	Myelodysplastic syndrome
NAD	Nicotinamide adenine dinucleotide (+)
ncRNA	Noncoding RNA
NF- κ b	Nuclear factor- κ b
OFR	Oxygen free radicals
PAZ	Piwi, Argonaut and Zwillie
piRNA	Piwi-interacting RNA
RNA	Ribonucleic acid
rRNA	Ribosomal RNA
RISC	RNA-induced silencing complex
SAM	S-adenosyl-L-methionine
SET	Su(var)3-9, Enhancer of Zeste, Trithorax
siRNA	Small interfering RNA
snoRNA	Small nucleolar RNA
Sumo	Small Ubiquitin-like Modifier
SOD	Superoxide dismutase
tRNA	Transfer RNA

UCRP	Ubiquitin cross-reactive protein
UFM-1	Ubiquitin fold modifier-
UBL5	Ubiquitin like protein-5
UBLs	Ubiquitin like proteins
Ub	Ubiquitin

1. EPIGENETIC MECHANISMS

The term epigenetics was first coined by C.H Waddington in 1942, a word derived from epigenesis and genetics. Epigenesis is the word for describing live organisms differentiating from a single cell into an organ or organism. Epigenetic mechanisms modulate gene expression patterns without affecting the deoxyribonucleic acid (DNA) sequence. To stop confusions, a consensus definition was put on use of the epigenetic trait: "stably heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence" [1]. These mechanisms are acquired throughout life and depend on environmental clues such as diet, lifestyle and toxin exposure. They are heritable mechanisms so epigenetic changes can be transferred to the new cell when cells are divided with mitosis. If this process takes place in germ cells and meiosis, genomic imprinting may occur. In some occasions, such as differentiation of embryonic stem cells to specific tissues, the expression is stabilized so that the cells cannot go back to their previous state. Although all cells in one individual have the same DNA sequence, epigenetic regulation occurs at the specific gene loci in the specific cells to yield specific cellular phenotypes. A change in the phenotype does not usually effect the genotype. Gene expression can be activated or silenced via epigenetic regulations. Epigenetic changes can alter transcriptional activity of genes, and may mediate the differences in risk for certain diseases. Methylation, phosphorylation, acetylation, ubiquitination, sumoylation are included in epigenetic processes.

Chromatins are complex macromolecules in cells. DNA, RNA, histones and non-histone proteins form chromatin structure. DNA is tightly packed into the nucleus in the chromatin structure, and this complex can be exposed to modification with acetyl groups (acetylation), non-coding RNAs like microRNAs (miRNAs) and small interfering RNAs (siRNAs). These modifications may cause changes in chromatin structure which in turn effect the expression patterns of the genes. So to summarize, epigenetic modifications are typically divided into three categories: (1) DNA methylation (2) histone post-translational modifications and (3) microRNAs.

1.1. DNA Methylation

DNA methylation can be briefly explained as covalent addition of a methyl group (CH₃) to the 5-carbon of cytosine forming 5-methylcytosine (5-mC) mostly located at cytosine-phosphate-guanine sites (CpG sites) that are present in the 5'-untranslated regions of gene promoters. Although DNA methylation usually ends up with suppression of gene transcription due to binding of methyl groups into the major groove of DNA, this process is essential for development and directly associated with processes in the cell such as X-chromosome

inactivation, genomic imprinting and in carcinogenesis. 5-mC can be hydroxylated forming 5-hydroxymethylcytosine (5-hmC) which consists of approximately 1.5% of human DNA [2]. DNA methylation is carried out by DNA methyltransferase (DNMT) activity, and methyl group donor is S-adenosyl-L-methionine (SAM). DNMTs are family of enzymes which catalyze the transfer of methyl groups to DNA. DNMT in mammals contains two main regions, C terminal region and N-terminal region. The C-terminal is the catalytic part containing approximately 500 amino acids, and this is the part which center of enzyme is located. The N terminal includes 621 amino acids, and is not vital for DNMT1 activity [3].

Although DNMTs have been classified in four groups since many years including DNMT1, DNMT2, DNMT3a, and DNMT3b, in mammals, there are actually three types of methyltransferases: DNMT1, DNMT3a, and DNMT3b [4]. DNMT1 is the major methyltransferase for maintenance of methylation, for this reason it is usually called as maintenance methyltransferase [5]. It catalyzes the transfer of a methyl group from SAM on to the 5' position of the cytosine ring, generating 5-methylcytosine. DNMT2 which used to be known as a DNMT, now termed as TRDMT1, is not a methyltransferase, even though its sequence is strongly associated with other DNMTs. Its DNA methylation activity is very low [6]. It only has a C domain and probably has a role in recognition of DNA damage and mutation repair [7]. DNMT2 (TRDMT1-tRNA aspartic acid methyltransferase 1) has both ribonucleic acid (RNA) methyltransferase activity and 5-cytosine DNA methyltransferase activity [8]. Previous studies have shown that DNMT2 functions as tRNA methyl-transferase by methylating cytosine-38 in aspartic acid of tRNA [8, 9].

DNMT3 can methylate both hemimethylated and unmethylated CpG at the same rate. DNMT3 family has three members which are DNMT3a, DNMT3b and DNMT3L. The structure of DNMT3 family is quite similar to DNMT1 and they have a catalytic domain with a regulatory region. DNMT3a and DNMT3b have different functions from those of DNMT1, they serve as *de novo* methyltransferases. For establishment and mitotic inheritance of tissue-specific DNA methylation patterns in normal development, *de novo* methylation is essential. It occurs frequently during early development and gametogenesis in mice to remethylate the repetitive sequences those are demethylated during early stage of embryogenesis [10].

DNA methylation results in gene silencing by the recruitment of methyl CpG-binding transcriptional repressors and by interfering with the DNA binding of transcriptional activators. Hypomethylated DNA is associated with active chromatin. Transcription level of DNA is affected by DNA methylation at the promoter region via two ways: (1) Methylated DNA prevents the binding of transcription factors to the gene promoter (2) methylated DNAs are occupied by methyl-CpG-binding domain proteins (MBDPs). MBDPs bring together the other epigenetic components consequently forming compact and inactive heterochromatin, therefore cause decreased or silenced gene transcription [11].

Aberrant DNA methylation on disease-related gene promoters was determined in various diseases, especially in cancer. DNMT inhibitors are promising therapeutic targets. Both Decitabine (5-aza-2'-deoxycytidine) and Azacytidine are hypomethylating agents. They show their function by inhibiting DNMTs. Decitabine can be incorporated into DNA where Azacytidine incorporates both into DNA and RNA [12], as azacytidine is the chemical analogue of DNA and RNA. Both of the drugs have been approved by the FDA for treatment of myelodysplastic syndrome.

1.2. Histone Post-translational Modifications

In eukaryotic organisms, DNA is wrapped around a protein octamer. This octamer is composed of two units of H2A, H2B, H3 and H4 histone proteins which are linked to each other through a linker protein called H1 histone. This complex unit is called as nucleosome and is the basic unit of the chromosomes. Histones can undergo post-translational covalent modifications which are phosphorylation on serine or threonine residues, methylation on lysine or arginine, acetylation and deacetylation on lysines, ubiquitylation of lysines and sumoylation on lysines [13, 14]. The best defined histone modification is acetylation. Histone modifications are proposed to affect chromosome structure and function, especially during transcription and chromatin remodeling processes. Core modifications of histones can also act on DNA templated processes, like replication and transcriptional processes. They can also effect nucleosomal structure [15, 16]. Simon et al. have shown that histone posttranslational modifications within distinct structured regions of the nucleosome directly regulate the inherent dynamic properties of the nucleosome such as unwrapping and disassembly [17]. North et al. have shown that phosphorylation of H3(T118) alters nucleosome dynamics and remodeling [18]. Histone modifications are catalyzed by histone modification enzymes such as histone acetyltransferases, histone deacetylases, histone methyltransferases and histone demethylases.

Histone acetyltransferases (HAT) acetylate conserved lysine residues on histone tails. HATs transfer an acetyl group from acetyl co-enzyme A (CoA) forming ϵ -N-acetyllysine. Depending on their localization, HATs (EC 2.3.1.48) are classified into two groups, the ones localized in the nucleus and carrying a conserved motif are Type A HATs, and the ones localized in the cytoplasm are Type B HATs [19]. Type A HATs also have three primary subclasses which are 1) GNAT (Gcn5-related N-acetylases) (Gcn5, PCAF and elongator complex protein 3(ELP3)) 2) MYST (HMOF/MYST1, HBO1/MYST2, MOZ/MYST3, MORF/MYST4, Type60 and Type p300/CBP (p300 and CBP) families.

The acetylated lysine is neutralized from positive charges (normally, the histone tails are positively charged which help these tails interact with negatively charged phosphate groups found on DNA backbone), and this acetylation decreases the electrostatic interaction between DNA backbone and histone tails. This mechanism is used to control gene expression by activating and inactivating genes on DNA. Simply, HATs are transcriptional co-activators and can promote transcription factors for activation of transcription. Acetylation of nucleosomes by HATs helps transcription factors to reach the DNA more easily so that transcription can increase.

Histone deacetylases (EC 3.5.1.98, HDAC) remove acetyl groups from an ϵ -N-acetyl lysine amino acid on histone tails, therefore the histones can wrap tighter around the DNA which helps to regulate the expression of a gene. The density of wrapping can alter expression levels. HDACs are transcriptional co-repressors. HDACs usually inactivate gene expression [20]. Depending on their sequence homology and subcellular localization, HDACs can be classified into four classes as I, II (a and b), III and IV. HDAC. Class I, (HDACs 1, 2, 3, and 8) are localized in the nucleus. Class II (HDACs 4, 5, 6, 7, 9, and 10), Class III (SirT 1, 2, 3, 4, 5, 6 and 7) and Class IV HDACs (HDAC 11) can be localized either on nucleus or cytoplasm. Class III HDACs can also be localized in the mitochondria [21, 22]. HDAC Class I, II and IV are zinc-dependent which are all expressed in the brain [23], whereas HDAC III is nicotinamide adenine dinucleotide (NAD⁺) dependent. Although Class I HDACs are known as nuclear enzymes, they were shown to play a role in unfolded protein response by localizing to the

endoplasmic reticulum [24]. In addition to their gene silencing function, sirtuins are the key regulators of multiple biological and metabolic events including energy metabolism, glucose and lipid metabolisms, circadian rhythms, inflammation, stress resistance, apoptosis, and autophagy. Many scientists have performed studies on HDACs and their functions in various diseases to find out the underlying epigenetic mechanism.

HDAC 2 is expressed in the central nervous system (CNS) and has a negative effect on memory and synaptic plasticity. Guan et al. have shown that binding of HDAC2 to the promoters of synaptic-plasticity-related genes and thereby negatively regulates their transcriptions [25]. Graff et al. have knocked down HDAC2 by short-hairpin-RNA and they have shown that structural synaptic plasticity and memory impairments were restored in mice [26]. These findings support the information that HDAC2 is associated with disrupted brain functions in neurodegenerative diseases.

Histone deacetylase inhibitors (HDACi) cause to an increase in histone acetylation and reduce the affinity of the histone to the negatively charged DNA backbone. By this method, chromatin gets less dense so that the transcription factors have the chance of reaching the DNA and increasing gene expression. Certain non-histone proteins (DNA repair proteins, DNA binding proteins, transcription factors, chaperones) are also substrate for HDACs. Therefore HDACs take place in various pathways including inhibition of DNA repair, induction of apoptosis, generation of reactive oxygen species (ROS), inhibition of cell cycle arrest and inhibition of antiangiogenesis [27]. In this context HDACi are considered as an emerging therapeutic target for cancer [28, 29] and HIV [30].

Histone methyl transferases (HMTs) (2.1.1.43 EC) are the enzymes (e.g; histone-lysine N-methyltransferases and histone-arginine N-methyltransferases) which modify the histones. They function in adding methyl groups to lysine (K) and arginine (R) residues. Lysine methyltransferases catalyze mono-, di-, and trimethylation of the lysine ϵ -amino group. Histone methylation can be managed by SAMs as the methyl group donor [31]. HMTs are composed of two classes, lysine specific or arginine specific. Lysine-specific HMTs have two subgroups which carry a special type of protein domain called SET (Su(var)3-9, Enhancer of Zeste, Trithorax) domain containing and non-SET domain containing. Histone methylation controls histone-protein interaction. It mediates the binding of HDACs to histones, thus silences the gene indirectly.

Ubiquitination (Ubiquitylation) of histones is required for histone methylation. Ubiquitin (Ub) is a regulatory protein and is found almost in any tissue of eukaryotes. Ubiquitination may cause the proteins to degrade with proteasomes, change their locations in the cell and increase or decrease protein-protein interactions [32]. Ubiquitination may also play major roles in apoptosis, cell cycle, DNA transcription and repair, response to oxidative stress and many other mechanisms. The protein to be ubiquinated must be activated, conjugated and ligated. These steps can be managed by ubiquitin-activating enzymes (E1s), ubiquitin-conjugating enzymes (E2s), and ubiquitin ligases (E3s), respectively. Ubiquitin first activates E1 and then it is transferred to E2. E3 Ubiquitin ligases are activated by a E2-Ub complex [33]. At the end of this process, ubiquitin is bound to lysine residues on the protein's N-terminus or the protein substrate. The binding can be either with a peptide bond or an isopeptide bond, respectively [34]. In general, defects in ubiquitination mechanism can alter the functions of the genes and proteins. Ubiquitination is associated with many types of disease including cancer, neurodegenerative and inflammatory diseases. [35, 36]. Ubiquitination of histone proteins is required for histone methylation, therefore silences the gene indirectly.

Although ubiquitin is the most studied and commonly known protein, another family of ubiquitin like proteins (UBLs) also exist. These proteins act like ubiquitin and modify proteins but they have distinct functions. One of the major members of this family is Sumos. Small Ubiquitin-like Modifier (Sumo) proteins are a family of small proteins comprising approximately 100 amino acids. Sumoylation is directed by an enzymatic cascade analogous to that involved in ubiquitination but SUMO modification usually functions on the opposite direction of ubiquitination and can help stabilizing protein substrates. As a post-translational modification, sumoylation plays different roles in cellular mechanisms, transportations, apoptosis and response to oxidative stress. Sumoylation regulates protein-protein interaction and localization, and enhances the interaction between histones and HDACs. Therefore it is involved in gene silencing, indirectly. Other members of UBLs include, but not limited to, ubiquitin cross-reactive protein (UCRP), ubiquitin fold modifier- (UFM-1), ubiquitin like protein-5 (UBL5), human leukocyte antigen F-associated (FAT10), autophagy-8 (ATG8), autophagy-12 (ATG12) and many others.

Carbonylation, mostly occurring on lysine and arginine residues, is a consequence of oxidative stress and it is mostly irreversible. Carbonylation causes loss of protein function, the modified proteins are aggregated and they accumulate as unfolded or damaged proteins. [37]. Sharma et al. have shown histone carbonylation to occur on histones H1, H2A, H2B and H3 but not H4 in rat liver. Contrary the wide belief that carbonylation increases by age, they have found the carbonylation was lower in older rats [38].

Besides these most frequently investigated post translational modifications, there are many other modifications such as *acylation* (*alkanoylation*- addition of functional groups on proteins such as addition of fatty acids to amino acids), *alkylation* (transfer of an alkyl group to another molecule, most common form is methylation with a distinction, in methylation only one carbon is transferred while in alkylation long chain of carbon groups are transferred), *glycosylation* (enzymatic addition of sugar molecule to a protein substrate to help proteins folding correctly, stabilize proteins, prevent protein degradation), *glycation* (non-enzymatic glycosylation, covalent binding of a protein with sugar molecule), *biotinylation* (covalent binding of biotin to a protein target), *neddylation* (conjugation of ubiquitin-like protein NEDD8 to protein substrates), *succinylation* (addition of succinyl group to a lysine residue), *sulfation* (addition of a sulfate group to a tyrosine residue).

1.3. Micro RNAs and Epigenetic

Small noncoding RNAs (ncRNAs) are functional RNA molecules which do not encode a protein. Even though they are not translated into a protein, they play major roles in cellular and molecular mechanisms. The family of ncRNAs include micro RNAs (miRNAs), transfer RNAs (tRNAs), ribosomal RNAs (rRNAs), small interfering RNAs (siRNAs), Piwi-interacting RNAs (piRNAs), and small nucleolar RNA (snoRNAs).

miRNAs are a family of short non-coding RNAs of approximately 19-25 long nucleotides which modulates the expression of mRNA. They play crucial roles in cell proliferation, apoptosis, cell cycle control, differentiation and cellular metabolism. miRNAs are found in serum, plasma, saliva, and other body fluids of humans and also in other organisms such as plants, animals and some viruses. Their regulation of gene expression is at post-transcriptional

level. miRNAs bind to target mRNAs at their 3'-untranslated regions and suppress their translation and/or promote their degradation, thus sequence-specifically control the translation of target mRNAs [39]. In addition, miRNAs bind complementary sequences on DNA and block access for transcription factors, which in turn results in turned off genes. miRNAs may show their functions on many different targets and a gene can be regulated by different miRNAs [40].

A miRNA is produced from a RNA-coding gene or from introns. It is thought that about 40% of all miRNA genes are located in the introns of protein coding or non-coding genes [41]. miRNAs start their life as primary transcripts known as a pri-miRNAs which are transcribed by RNA polymerase II in the nucleus and they carry a 5' cap and a poly-A-tail. The pri-miRNAs are then transcribed to pre-miRNA, a 70 nucleotide long structure, in the microprocessor complex consisting of RNase III enzyme Drosha and dsDNA binding protein DGCR8 (DiGeorge Syndrome Critical Region 8- Pasha in invertebrates). The pre-miRNAs are imported out of the nucleus into the cytoplasm by RAN-GTP complex and exporting 5 (Exp5) protein. This complex plays an important role in translocation of the RNA and proteins through the nuclear pores. When pre-miRNAs are out of the nucleus, Dicer, a RNase III enzyme containing an ATPase/RNA helicase, a DUF283 (Domain of unknown function) domain, a PAZ (Piwi, Argonaut and Zwiille) domain, two catalytic RNase III domains (RIIIa and RIIIb), and a C-terminal double-stranded RNA-binding domain (dsRBD), cleaves the pre-miRNA stem loop into two complementary RNA molecules but only one of these molecules integrate with the RNA-induced silencing complex (RISC), resulting with mature miRNA.

Even though the biogenesis of miRNA has been extensively studied, the regulation of miRNA expression still needs to be clarified. A miRNA can be localized in various regions of the genome. If they are localized between the genes, they are called intragenic, if the localization is in the gene they are called intergenic. In an *in silico* analysis by Sato et al. it has been shown that of 939 miRNAs, 293 (31.2%) were intergenic, whereas 317 (44.4%), 119 (12.7%) and 110 (11.7%) were overlapped by RNA transcripts in the same, opposite and both directions, respectively [42].

There are numerous studies investigating the relationship between miRNA and epigenetic regulations in various diseases such as cancer, diabetic, neurologic and inflammatory related diseases, aging and this number is still growing. Even though the underlying mechanism is not clearly understood, miRNA dysregulation is determined in all of these pathologies. It is thought that miRNAs contribute to formation of diseases via epigenetic regulations, and miRNA modulation is a new therapeutic approach that is extensively investigated in various diseases.

2. OXIDATIVE STRESS

Living organisms mostly rely on oxygen. Oxygen is like a double-edged knife. The cells of living organisms cannot live without oxygen but oxygen and its radical species can also harm cells by reacting with cellular components. Impaired balance between the oxidants and the anti-oxidants may cause a damage to the cells and this is called the oxidative stress. If the body cannot fight against the harmful reactive oxygen species, with another word oxygen free radicals (OFR), such as O_2^- (superoxide radical), $OH\cdot$ (hydroxyl radical), triplet oxygen, triplet carbene ($:CH_2$) and H_2O_2 (hydrogen peroxide), they may cause irreversible damage on the

cellular components such as DNA, proteins, lipids. This damage may even cause stop cellular signaling which is essential for the viability, motility and production of the cell.

According to IUPAC (International Union of Pure and Applied Chemistry) a free radical can be an atom, a molecule or an ion that has unpaired valence electrons [43]. These free radicals are highly reactive with other molecules. As they have an unbalanced structure and lacking of electrons, they are very prone to interact with other molecules in order to steal their electrons from them. They can even react with each other to form dimers, trimers or polymers. The most infamous radicals are superoxide anion (O_2^-) and hydroxyl radical ($OH\cdot$). O_2^- is formed after one electron reduction of dioxygen (O_2). Superoxides are toxic substances and produced by the immune system to be used against foreign substances. In case of a dismutation of superoxide, molecular oxygen (O_2) and hydrogen peroxide (H_2O_2) are formed and this reaction is catalyzed by superoxide dismutase enzyme (SOD-E.C 1.15.1.1).

SOD

The main source of OFR in the cells is the leakage from mitochondrial electron transport chain especially from complex I (NADH dehydrogenase) and III (coenzyme Q and cytochrome C oxidoreductase) [44]. When components of the oxidative phosphorylation located in the inner membrane of the mitochondria are reduced, production of mitochondrial superoxide radical increases. Superoxide radical and hydroxyl radical start the lipid peroxidation in cytoplasm, nucleus, mitochondria and endoplasmic reticulum which increases membrane permeability. Due to effect of OFR proteins, nuclear and mitochondrial DNA are oxidized. Oxidation of proteins may result in functional loss. OFR attacks to DNA causes DNA strand breaks and base modifications. Among the oxidized bases, 8-hydroxydeoxyguanosine (8-OHdG) is the most mutagenic lesion. By mispairing with A residues, 8-OHdG leads to an increased frequency of spontaneous G:C $\rightarrow$ T:A transversion. This mutation is recorded in many mutated proto-oncogenes and tumor suppressor, and 8-OHdG is strongly implicated in the initiation of carcinogenesis.

As mentioned above, free radicals can steal electrons from other atoms, destabilizing and perturbing them. In order to overcome this attack, the body uses antioxidants. Antioxidants are used to neutralize OFR before they harm the cells. They can be classified in two main groups, endogenous and exogenous antioxidants. Endogenous antioxidants can be sub-grouped into two as enzymatic antioxidants and non-enzymatic antioxidants. The first one includes the enzymes such as Superoxide dismutase (SOD), Glutathione S-Transferases (GST), Glutathione Peroxidases (GSH-Px), Catalase (CAT), mitochondrial cytochrome oxidase system, whereas the latter group consists of selenium, melatonin, hemoglobin, glutathione, bilirubin, methionine, retinal, thiols, and many others. Exogenous antioxidants can be classified as vitamins (ascorbic acid, alpha tocoferol, beta carotene, folic acid), drugs (xanthine oxidase inhibitors, NADPH oxidase inhibitors etc.) and nutrient antioxidants (sodium benzoate, catechins, anthocyanins, tannins, lycopene, etc.)

Due to the damaging effects on cellular macromolecules, OFR contribute to pathogenesis of many diseases including cancer, ageing, neurodegenerative diseases, obesity, cardiovascular diseases, neuroinflammation, etc. [45-49]. It has been recently recognized that OFR also modulate epigenetic mechanisms.

3. INTERACTIONS BETWEEN OXIDATIVE STRESS AND EPIGENETIC MECHANISMS

OFR may modulate epigenetic mechanisms. They can effect epigenetic mechanisms in various ways: 1) OFR changes the pattern of DNA methylation 2) Oxidative stress reduces methyl-accepting ability of DNA 3) OFR cause changes in histone modifications [50].

3.1. Oxidative Stress - DNA Methylation

Distruption of DNA methylation patterns by OFR is the best defined in carcinogenesis. Briefly, the hypermethylation of the DNA can cause gene silencing resulting with decreased gene expression, uncontrolled cell proliferation and growth which may end up with cancer. On the other hand, hypomethylation may cause loss of imprinting and chromosomal instability [51, 52]. Hydroxyl radical-induced DNA lesions such as 8-hydroxy-2-deoxyguanosine (8- OHdG) have been shown to contribute to decreased DNA methylation. 8- OHdG adducts interfere with the ability of DNA to function as a substrate for DNMTs. This results in global hypomethylation of the genome which in turn leads to oncogene activation and chromosomal instability. In addition, OFR are responsible for gene silencing by leading aberrant hypermethylation in CpG island-rich promoter region of tumor suppressor genes [53]. Many tumor suppressor genes have been found to be silenced via OFR-mediated aberrant methylation of promoter regions [54-57]. Recent studies have shown a further modification on the methylated CpGs which may make the gene less prone to transcription than those in the methylated state. This further modification is hydroxylation of 5-methylcytosine. Oxidative stress results in hydroxymethylation of DNA, especially in neurons [58]. Regarding other diseases, Patchsung et al. have demonstrated a relationship between increased oxidative stress and hypomethylation of the transposable long-interspersed nuclear element-1 (LINE-1) in patients with bladder cancer. They have found that LINE-1 hypomethylation levels and the number of hypomethylated loci in both the blood- and urine-derived cells are increased which is also causing an increase in oxidative stress in the bladder cancer patients [59]. In patients with myelodysplastic syndrome (MDS), two tumor suppressor genes, P15 and P16, have been found to be hypermethylated due to oxidative stress caused by peroxides, superoxide anion in leukocytes (CD45+ cells) from bone marrows of the patients [60]. This situation may be interpreted as hypermethylation of tumor suppressor genes cause them stop functioning thus increase the chance of cancer progression. Gu et al. have studied histone acetylation and DNA methylation, involved in the transcription of Alzheimer's disease-related genes in human neuroblastoma cells which is treated with hydrogen peroxide. They have found that expression of amyloid- β precursor protein and β -site amyloid- β precursor protein-cleaving enzyme 1 is upregulated due to demethylation in the gene promoters associated with the reduction of methyltransferases. They have also shown down-regulation of HDACs in the same cells. They have concluded that oxidative stress causes an imbalance between DNA methylation and demethylation, and histone acetylation and deacetylation [61]. In fact, both DNMTs and HDACs are vulnerable to oxidative stress due to their protein structure. Increased oxidative stress may inactivate them that results in impaired epigenetic pattern.

3.2. Oxidative Stress - Histone Post-Translational Modifications

Addition of a methyl or phosphate group to histones does not directly affect chemistry of histone. However, acetylation of histone tails directly alter gene expression that higher acetylation of the histones ends up with higher level of transcription. Probably due to this reason, studies examining the effect of oxidative stress on histone post-translational modifications have been focused on acetylation/deacetylation rather than other modifications. OFR- dependent signaling pathways prompt transcriptional and epigenetic dysregulation. Oxidative stress induces various kinase signaling pathways leading to histone acetylation/deacetylation. Activation of upstream kinases, such as nuclear factor- κ B (NF- κ B)-inducing kinase, mitogen and stress-activated kinase-1 by OFR results in downstream chromatin remodeling, which in turn alters the function of gene promoters [62]. In this context, OFR-mediated epigenetic alterations are especially shown to modulate transcription of specific genes that control apoptosis, autophagy, senescence, proliferation, transformation, and differentiation [63]. Although all histone modifying enzymes may be oxidized by OFR, sirtuins are more vulnerable due to their dependency to NAD^+ . When OFR interact with DNA, strand breakage occurs. This is a signal for polyADP ribose polymerase activation, the enzyme that uses NAD^+ . Increased oxidative stress may lead intracellular NAD^+ depletion and decreased sirtuin activity. Since sirtuins have a regulator function on various biological pathways, its low activity results in impaired cellular function. p53 is one of the major targets of SIRT1. Decreasing SIRT1 activity increases p53 acetylation, which in turn promotes apoptosis and senescence [64]. Oxidative stress has been shown to accelerate cellular senescence, due to increased p53 acetylation via decreasing the function of SIRT1 through NAD^+ depletion [65].

3.3. Oxidative Stress – miRNAs

miRNAs are not translated into a protein but play a crucial role in regulation of gene expression via translational repression or mRNA degradation. Although OFR-induced gene regulation has been extensively studied at epigenetic level, the effects of OFR on gene expression regulation by miRNAs is currently uncertain. Certain studies have shown that miRNAs are involved in regulation of cell survival in response to oxidative stress [66, 67]. The activation of apoptosis by Fas death receptor is stimulated by OFR. In an in vitro study Lin et al. have demonstrated that Fas is a functional target gene for miR-23a, forced overexpression of miR-23a reduces cell death induced by H_2O_2 incubation in macular retinal pigment epithelial cells, and this protective effect of miR-23a is disappeared by miR-23a inhibition [68].

In fact, it should be kept in mind that miRNAs are encoded by miRNA genes and their expressions are mostly regulated by epigenetic mechanisms. Epigenetic mechanisms may affect the expression of miRNAs in both physiological and pathologic conditions in a tissue-specific manner [69]. Hyper or hypo methylation of miRNA coding gene promoters leads to altered miRNA expression patterns, and this event may result in different diseases including cancer, glioblastoma, Parkinson's disease and Alzheimer's disease [70, 71]. Furthermore, recent studies have revealed that miRNAs are transcriptionally regulated by a variety of DNA methylation-specific methyl-CpG-binding domain proteins (MBDs) [72]. Besides DNA methylation, histone post-translational modifications and associated changes in chromatin

structure can affect miRNAs at the transcriptional level leading their both up- and down regulation [73].

CONCLUSION

Eukaryotic organisms including human beings are very complex structures and a variety of mechanisms interact with each other. Genetic and epigenetic changes work hand by hand to keep this fabulous factory working. Aberrant epigenetic modifications and regulations in post-transcriptional and post-translational processes make either direct or indirect contributions to the diseases such as cancer, neurodegenerative and inflammatory diseases. Oxidative stress is a state of persistent generation of OFR overwhelming cellular antioxidant defense, and it has long been known to contribute to pathogenesis of various diseases. Although harmful effects of oxidative stress on genes have been discovered a long time ago, OFR-epigenome interaction and its consequences have gained interest in the last decade. OFR-induced epigenetic mechanisms involve changes in DNA methylation profiles, histone acetylations and miRNA expression. Epigenetic modifications are potentially reversible and there is a great potential for the development of effective strategies to cure diseases. Scientist all over the world are studying on different mechanisms and interactions of genes and proteins to find cures for diseases. Understanding the role of oxidative stress on epigenetic mechanisms can help to see light at the end of the tunnel.

ABSTRACT

Cancer is one of the deadliest malignancies that have plagued mankind for decades. Epigenetic mechanism(s) play a central role in the homeostasis of normal cell proliferation and differentiation. Global epigenetic modifications are frequently associated with cancer initiation, progression, as well as metastasis. These changes include DNA methylation, histone lysine methylation/demethylation, acetylation/ deacetylation, including methylation and acetylation of non-histone proteins, and can alter the expression of various oncogenic signaling cascades, which in-turn can lead to uncontrolled proliferation. In this chapter, we primarily focus on the major epigenetic changes that occur in oncogenes, tumor suppressor genes, transcription factors and cancer stem cells, which in turn mediate tumor growth. These modifications are controlled by regulatory enzymes such as DNA methyltransferase, histone acetyltransferases, histone deacetylase, lysine acetyltransferase, and arginine and lysine methyl transferases. In addition, we also describe a few selected pharmacological agents that can modulate the action of these enzymes and display significant potential for cancer therapy.

Keywords: cancer, epigenetics, transcription factors, oncogenes

ABBREVIATIONS

ALL	acute lymphocytic leukemia
AML	acute myeloid leukemia
APC	adenomatosis polyposis coli
ASH2L	absent, small or homeotic discs-like 2
AR	androgen receptor
BRCA1	breast cancer 1, early onset
COX	cyclooxygenase
CML	chronic myelogenous leukemia
CARM1	coactivator associated arginine methyltransferase 1
Cdk9	cyclin dependent kinase 9
CDKN2	cyclin dependent kinase 2
CpG	cytosine-phosphate-guanine
CREB	c-AMP response element binding protein
CSC	cancer stem cell
CDH1	E-cadherin
CREB	cAMP response element binding
CBP	cAMP response element binding (CREB) protein
CTL	cytotoxic T-Lymphocytes
DAPK1	death associated protein kinase 1
DLBCL	diffuse large B-cell lymphoma
DNMT	DNA methyltransferase
DR	death receptor
EZH2	enhancer of zeste 2 polycomb repressive complex 2 subunit
ERRB2	human epidermal growth factor receptor 2
EMT	epithelial-to-mesenchymal transitions
ER	estrogen receptor
FDA	food and drug administration
FBXL11	F-box and leucine-rich repeat protein 11
GNAT5	Gcn5-related N-acetyltransferase
GSTP1	glutathione S-transferase-pi
GM-CSF	granulocyte macrophage colony stimulating factor
GSK3 β	glycogen synthase kinase 3 β
HCC	hepatocellular carcinoma
HIF1	hypoxia-inducible factor
HRE	HIF1 α binding to the HIF1 α -response element
H3K27me3	trimethylated lysine 27 on histone H3
H3K4me	
1/2/3	mono-di-tri-methylated histone H3 at lysine 4
H3K64me3	trimethylated histone 3 at lysine 64
H3K9ac	acetylated histone H3 at lysine 9
H3K9me	
1/2/3	mono-di-tri-methylated histone H3 at lysine 9
H4K20me3	trimethylated histone 4 at lysine 20

HMG	high mobility group
HSC	hematopoietic stem cells
IGF	insulin like growth factor
IKK	I κ B kinase
IL	interleukin
JAK	janus kinase
JmJc/N	jumonji-domain-containing protein histone lysine demethylases
KAT	histone lysine acetyltransferases
KATi	histone lysine acetyltransferases inhibitor
KDAC	histone lysine deacetylase
KDACi	histone lysine deacetylase inhibitor
KMT	histone lysine methyltransferases
KDMs	histone lysine demethylases
MBD	methyl-binding domain
MBD2	methyl-CpG-binding domain protein 2
MBD3	methyl-CpG binding domain protein 3
MHC	major histocompatibility complex
MLL	histone methyl transferase
MOZ	monocytic leukaemia zinc finger protein
MKP1	mitogen activated protein kinase (MAPK) phosphatase-1
NSD1	nuclear receptor binding Su(var)3–9, enhancer of zeste and Trithorax (SET) domain protein 1
iNOS	inducible nitric oxide synthase
NF- κ B	nuclear factor kappaB
NFAT	nuclear factor of activated T cell
PG	prostaglandins
PPAR- γ	proliferator-activated receptor gamma
PTEN	phosphatase and tensin homolog
PARP-1	poly-ADP-ribose-polymerase 1
PCAF	p300/CBP associated factor
PcG	polycomb group of proteins
PR	progesterone receptor
PRC2	polycomb repressive complex 2
PRMT	protein arginine methyl transferases
PHF	plant homeodomain (PHD)-finger protein
PKMT	protein lysine methyl transferase
PKDM	protein lysine demethylases
RASSF1	ras association domain-containing gene
RelA	v-rel avian reticuloendotheliosis viral oncogene homolog A
SAM	s-adenosyl methionine
SMYD	SET and MYND-domain containing
SIRT	sirtuin
Skp2	S-phase kinase associated protein 2
STAT3	signal transducer and activator of transcription
TLR	toll like receptor

TGF β	transforming growth factor beta
TIMP-3	tissue inhibitor of metalloproteinase 3
TNF α	tumor necrosis factor alpha
TSA	trichostatin A
VHL	Von Hippel–Lindau

1. INTRODUCTION

Historically, epigenetics is defined as heritable changes in gene expression patterns that occur without any changes to the DNA but involve changes that are adequate to regulate activation or repression of gene expression. The term epigenetics was first introduced by developmental biologist Conrad H. Waddington in 1942. The latest revised definition of epigenetics includes the transient changes that occur during gene expression [1]. Epigenetics is an important physiological process that occurs all through the development and differentiation of any organisms that have the same set of DNA sequences, and drives them to diversify into different cell types [2]. In addition to its pivotal role in the development of an organism, deregulated epigenetics mechanisms are often encountered in the development and severity of disease. It is now increasingly apparent that chronic inflammation-driven diseases occur due to both genetic and epigenetic alterations [3, 4]. It was Rudolf Virchow in 1870 who linked inflammation with cancer, diabetes, obesity, arthritis, allergy, and atherosclerosis [5]. From then on the connection between inflammation and cancer development has been frequently observed in chronic inflammatory bowel disease and colorectal cancer [6], Barrett's esophagitis and esophageal cancer [7], and in virus-induced cancers such as human papilloma virus-induced cervical cancer, hepatitis B or C virus-induced liver cancer [8]. It has been estimated that 15% of all cancers are linked to inflammation [6]. In addition, environmental factors such as exposure to radiation are also key contributors in cancer progression [7]. The first and foremost defense response to any type of injury to the human body is the recruitment of immune cells such as leukocytes, lymphocytes, neutrophils, monocytes, and macrophages. These cells reduce the inflammatory reaction in an acute attack. However, in chronic inflammation, pro-inflammatory molecules are produced and secreted by these cells, which produces a cascading effect and thus, has been implicated in the development of various major human diseases including malignancies [9]. Thus, excessive production of pro-inflammatory molecules such as cytokines, chemokines, prostaglandins (PGs), nitric oxide (NO), and leukotrienes deregulate the cellular signaling and transcriptional mechanism(s), which ultimately leads to the development of neoplasms [10]. Thus, changes to the epigenome mediated by various enzymes are now been recognized as being important mediators in the activation or silencing of genes, the impact of which are as significant as heritable permanent genetic mutations in the DNA [11]. The impact of epigenetic alterations in disease progression has led pharmaceutical companies to target these histone and non-histone modifying enzymes for anti-cancer drug development [12-14].

In the eukaryotic cell nucleus, DNA is wrapped around the core histone octamer H2A, H2B, H3 and H4, thus forming the fundamental unit of chromatin, the nucleosome [15]. Post-translation modifications on core histone tails, along with cytosine methylation of the DNA, determines the accessibility of the chromatin and thereby enhancing the ability of transcription

factors to bind to DNA and initiate gene transcription [15]. These transient changes are unstable and disappear very rapidly, and can be easily modulated by any external stimulus [15, 16]. In contrast to transient change, permanent change to the DNA often leads to underdeveloped or defective organs and to the development of diseases. These heritable permanent DNA changes often occur at specific dinucleotide sites along the genome such as the cytosine 5' of guanine (CpG) sites. It has been observed that 40% of genes contain clusters of CpG dinucleotide upstream of the transcription start site and are often found to be 70-80% methylated [17, 18]. Escalation in DNA methylation is often seen in chronic inflammation-driven diseases, viral infections, and cancers. Thus, aberrant DNA methylation now serves as a biomarker for the early detection of cancer and can also be related to the therapeutic effectiveness of drugs affecting DNA methylation and histone acetylation [4]. Epigenetic modifications of chromatin and DNA have in recent times been acknowledged as being either the expressive or suppressive factors in directly controlling gene transcription [18]. The post-translation modification on histone proteins in chromatin and methylation of DNA are regulated by two distinct pathways [18]. Environmental factors influence the epigenome at all times during the development of human life, especially nutritional factors, which can have profound effects in the expression of specific genes by epigenetic modifications [19]. The epigenome is characterized by global hypomethylation, but distinct CpG islands located in the regulatory regions of genes can be hypermethylated, leading to repression of gene expression [20]. Based on the levels of methylation status of CpG islands, monoallelic silencing and other epigenetic regulatory mechanisms have been reported in key inflammatory response genes [11, 18]. Histone hypermethylation silences genes involved in cell cycle control (*CDKN2*) [21], apoptosis (*DAPK1*) [22], DNA repair (*BRCA1*) [23], metastasis (*TIMP3*) [24], drug resistance, tumor heterogeneity, stem cell-like state [25], differentiation, epithelial-mesenchymal transition, metabolism [26], and VEGFR2 [27]. This global phenomenon of CpG hypermethylation is a common biological pathway to switching off genes. While DNA mutations have been linked to chronic inflammation-driven cancers, it is also observed that epigenetic alterations can contribute to familial cancer risk [28]. Chronic inflammation mediates the initiation of a variety of diseases including cancer progression, which can be explained on the basis of epigenetic dysregulation [29-32]. Recent studies have indicated that DNA hypermethylation and histone modifications play important roles in gene silencing [33].

Selective silencing of DNA methyltransferase leads to acute fatty acid-induced, non-CpG methylation of proliferator-activated receptor gamma (PPAR- γ) co-activator 1 alpha promoter [34]. In this chapter, we primarily focus on the major epigenetic changes that occur in oncogenes, tumor suppressor genes, transcription factors, and cancer stem cells, which in turn mediate tumor growth. These modifications are controlled by regulatory enzymes such as DNA methyltransferase, histone methylases, histone demethylases, histone lysine acetyltransferases, histone deacetylases, and arginine and lysine methyl transferases. In addition, we also describe a few selected pharmacological agents that can modulate the action of these enzymes and display significant potential for cancer therapy.

2. THE DYSREGULATION OF EPIGENETIC FACTORS IN VARIOUS CANCERS

2.1. The Deregulation of DNA Methylation in Cancer

DNA methylation is a widespread epigenetic modification in eukaryotic cells. DNA methylation occurs at the 5' end of the CpG dinucleotide of the cytosine ring, with S-adenosyl-L-methionine as its methyl donor [35, 36]. This reaction is catalyzed by a family of closely related DNA methyltransferases (DNMT), DNMT1, DNMT3A, and DNMT3B [37]. DNMT1 is the most abundant DNMT in mammals and maintains the methylation status on CpG dinucleotides [38]. In normal eukaryotic cells, the CpG islands are usually found in the unmethylated state to maintain euchromatin structure, and thereby allowing gene expression. However, during cancer development, many of the genes are hypermethylated at their CpG islands and silence gene transcription by changing the open euchromatic structure to a compact heterochromatic structure that is repressive for transcription [39]. DNMT1 predominantly adds a methyl group to DNA when one strand is already methylated (hemi-methylated) [40]. Once methylated they recruit the methyl-CpG-binding domain (MBD) proteins such as Kaiso, MeCP2, and members of the MBD family, which recognize methylated CpG islands and initiate chromatin silencing [41].

In cancer, promoter DNA hypermethylation has been observed for over two decades with the subsequent silencing of tumor suppressor genes [42, 43]. Global hypomethylation 'shores' also occur in cancer cells and are associated with genomic instability [44]. Both hypomethylation and hypermethylation have been seen across different types of cancers [45]. In cancer cells, hypermethylation are often observed in the promoter regions of tumor suppressor genes such as retinoblastoma gene (RB1), phosphatase and tensin homolog (PTEN), and DLC-1, glutathione S-transferase-pi (GSTP1), and E-cadherin (CDH1), thereby resulting in loss-of-function in colon cancers [46, 47]. Hypermethylation targeting of specific genes such as p16, p15, MINT1, MINT2, MINT31, MLH1, MSH2, MGMT, DAPK, APC, LKB1, IGF2, and COX2 has also been detected in colon cancer [47-49]. Global methylations have been observed in tumors of breast, prostate, lung, as well as in hematological malignancies [50, 51]. Overexpression of DNMT1 is widely reported in leukemias [51], and mutation and hypermethylation of this gene is observed in a variety of hematological malignancies [52]. Hypermethylation of genes such as GSTP1, RASSF1A, APC, MGMT, CCNA1, CDH1, RUNX3, ESR2, CDKN2A, RAR β 2, IGFBP7, and SFRP2 are all implicated in prostate cancer development and progression [53, 54], including E-cadherin, CD44, galectins [55], ER, androgen receptor, retinoic acid receptor, and genes involved in apoptosis [56], tissue inhibitors of metalloproteinases (TIMPs) [57], and cyclinD kinases [58]. In breast cancer, more than 100 genes have been hypermethylated in all type of cell processes including cell cycle regulation genes CCND2, p16ink4A/CDKN2A [59], apoptosis genes such as APC, TWIST, and HOXA5 [60, 61], metastasis, invasion genes such as RAR β 2, CDH1, ER, BRCA1, CCND2, p16 and TWIST, angiogenic genes VEGFR2, eNOS and in cell signaling pathways [62]. The estrogen receptor (ER) α and progesterone receptor (PR), which are critical in hormone regulation, are also frequently methylated in breast cancer [63]. DNA hypomethylation is also frequently reported in breast cancer, especially on FEN1 BCSG1, PLAUR, IGF2, and CDH3 [64, 65]. In addition, recent research has shown that miRNA that function as tumor suppressors can be

silenced via DNA methylation [66]. Lower levels of genome-wide DNA hypomethylation have been observed in metastatic prostate cancer in contrast to non-metastatic prostate cancer [67, 68]. Gene-specific hypomethylation also occurs in urokinase plasminogen activator (uPa), cell proliferation genes, and in various cellular processes such as invasion and metastasis [69], cancer/testis antigen gene [70], hydroxylation of estrogens [71], and X-chromosome inactivation [72]. In pancreatic carcinoma, DNA hypomethylation occurs in the promoter regions of the RASSF1A gene and K-Ras mutations [73]. Similarly, global hypomethylation and hypermethylation are also observed in lung cancer [74]. DNA hypomethylation in H19, IGF2, and MEST genes results in abnormal lung cancer growth. In NSCLC cancer, testis antigen and melanoma-associated antigen were upregulated due to hypomethylation [75]. Hypermethylation of tumor suppressor genes such as *p53*, *CDKN2*, *p16INK4* [21], *MGMT* [76], *DAPK*, *caspase 8*, *ARF*, *FAS*, *TRAILR1* [76, 77], *RASSF1A*, *NORE1A*, *G0S2*, *cadherins*, *TIMP3* [78, 79] may also result in their silencing.

2.2. The Deregulation of Histone Lysine Methylation in Cancer

ϵ -*N*-methyl-lysine was first found in a bacterial flagellar protein in 1959 [80] and subsequently, in 1964, this post-translational modification (PTM) was also identified in histones [81]. Other PTMs include acetylation, ubiquitination, phosphorylation, sumoylation, and ribosylation at histone tails [82-84]. Several reports have indicated that PTM do influence the density of chromatin and thus accessibility to DNA and gene transcription [84]. Core histones H2A, H2B, H3, and H4 combine to form the basic structure of the histone octamer, the nucleosome [84, 85]. Mono, di-, or tri-methylation of histones takes place in the amino acid of the N-terminal tail of histones that are prone to covalent modifications. It has been shown that methylation predominantly occurs in histone H3 or H4 lysine residues such as H3K4, H3K9, H3K27, H3K36, and H4K20, and one lysine residue located in H3 (H3K79) [86, 87]. Nuclear receptor binding Su (var)3-9, Enhancer of zeste and Trithorax (SET) domain protein 1 (NSD1) is the largest protein of the NSD family of histone lysine methyltransferases. It is located on chromosome 5q35 and consists of 2696 aa [88]. In the multi-domain NSDs, it is the SET domain that is responsible for methyltransferase activity. The NSD protein lysine methyltransferases (KMTs) family is composed of three members, NSD1 (KMT3B), NSD2 (WHSC1/MMSET), and NSD3 (WHSC1L1), which regulate gene expression through methylation of lysine 36 on histone H3 (H3K36) [89]. An accumulation of evidence has unveiled the role of NSDs in a variety of cancers due to genetic alterations or aberrant overexpression. Numerous studies have reported the role of NSD1 with a distinct *HOX* gene expression pattern in acute myeloid leukemia (AML) [90-93]. In addition to NSD1, NSD2 has also been implicated in cancer pathogenesis. NSD2 mRNA was found to be overexpressed in 13 types of cancers [94], and overexpression of NSD2 protein in 3774 tumor samples of colon, small cell lung, skin, multiple myeloma, and bladder cancer [88, 95]. In breast, prostate, oligodendroglioma, and head and neck cancers, NSD2 overexpression was associated with higher tumor grade [96]. A high level of NSD2 is an indicator of poor overall and disease free survival in hepatocellular carcinoma and endometrial cancer [97, 98]. In addition, NSD3 has been identified as the fourth most frequently amplified methyltransferase in breast cancer [99, 100]. However, histone tri-methylation on the lysine 4 residue of histone 3 (H3K4me3) leads to gene activation while tri-methylation on lysine 9 (H3K9me3) or on lysine 27 (H3K9me3)

leads to gene repression [19]. It is of note that histone methylation often leads to a condensed chromatin structure and thereby suppress gene expression [101]. EZH2 (KMT6) catalyzes the trimethylation of histone H3K27me3 [102] and initiates gene silencing via local chromatin reorganization. Several studies suggest that EZH2 plays a critical role in initiation, progression, and metastasis of prostate, breast, bladder, ovarian, renal carcinoma, lung, liver, brain, gastric, esophageal, pancreatic, and melanoma cancer, and also in cancer stem cells [102, 103]. In solid tumors, a hypoxic microenvironment induces hypoxia-inducible factor (HIF1) α binding to the HIF1 α -response element (HRE) and transactivates EZH2 transcription [104]. There are also other methyltransferases that are overexpressed in variety of cancers, such as KMT2A in human lymphoid and myeloid leukemias [105, 106], KMT1A in colon cancer [107], KMT1C in lung carcinoma [108, 109], Ash2L in hematological malignancies, hepatocellular carcinoma (HCC) and gastrointestinal cancers [110, 111], and SET and MYND-domain containing (SMYD)-3 in breast, colon, and HCC [112, 113]. Other lysine methyltransferases that are either mutated or downregulated in cancers are menin, KMT3B, and KMT8 [39, 114, 115].

2.3. The Deregulation of Histone Lysine Demethylases in Cancer

Lysine demethylases are a diverse group of demethylases. The lysine-specific histone demethylase (LSD) family and JmjC-domain containing histone demethylases (JHDMs) protein family have been identified as the two major families of demethylases that regulate histone demethylation, which are responsible for removing the methylation mark on lysines [82, 116-124]. LSD1 (KDM1A) and LSD2 (KDM1B) are flavin-dependent monoamine oxidases that can only demethylate mono- and di-methyl lysine and not tri-methyl lysine residues [117, 122, 125]. LSD1 demethylates H3K4me1/2 and H3K9me1/2, and non-histone proteins such as p53, E2F1, and DNMT1 [124]. LSD1 is overexpressed in prostate, breast, bladder, lung, colon, and neuroblastoma cancers [126], and is under expressed in HCC [111, 127]. LSD1 is also associated with mixed lineage leukemia (MLL) [128], and sustains the growth of MLL-AF9 acute myeloid leukemia cells by preventing differentiation and apoptosis [129], and serves as a biomarker for aggressive malignancies and tumor relapse [130]. It is of note that LSD1 upregulates cyclin A2 (*CCNA2*) and human epidermal growth factor receptor 2 (*ERBB2*) in aggressive breast cancer [130]. LSD2 is highly overexpressed in breast cancer and in invasive tumors, in contrast, a decreased expression of LSD2 is seen in leukemia and in seminoma [131]. The JmjC domain containing demethylases can demethylate mono-, di-, and tri-methyl lysine residues [120, 121, 124, 132]. Around 30 JmjC domain containing proteins have been identified in the human genome [133] and are divided into six sub-families based on histone lysine sites and demethylation states. They are KDM2, KDM3, KDM4, KDM5, KDM6, and plant homeo domain (PHD)-finger protein (PHF) [134]. JmjC domain-containing proteins belong to the Fe (II) and 2-oxoglutarate (2-OG)-dependent dioxygenases. They demethylate di- or tri-methylation marks on H3K4, H3K9, H3K27, H3K36, and non-histone proteins [124]. The KDM2 subfamily is comprised of KDM2A and KDM2B, which can demethylate H3K36A/B and the non-histone protein nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) [135]. KDM2A/B is also involved in cellular processes such as ribosomal RNA transcription, cell proliferation, apoptosis, differentiation, and carcinogenesis [136-138]. Overexpression of KDM2A/B is observed in bladder cancer, T-acute lymphocytic leukemia

(T-ALL), B-ALL, AML, breast, pancreatic adenocarcinoma, and seminoma. In contrast, reduced expression of KDM2A/B is observed in prostate cancer and glioblastoma [124, 139, 140]. In the human genome, the KDM4 family is sub-divided into two major groups based on their domain structure. KDM4A, KDM4B, and KDM4C form the first group while KDM4D, KDM4E, and KDM4F form the second group. The first group contains two PHD domains and two tudor domains in addition to the JmjC and JmjN domains, whereas the second group has only JmjC and JmjN domains [141]. KDM4A/B/C demethylates both histone and non-histone protein methylation such as WIZ, CDYL1, and G9a [142]. Therefore, KDM4 demethylases act as either repressors or activators of transcription and are involved in regulating various cellular processes including cell cycle and DNA damage repair, as well as tumor initiation and progression [124, 143, 144]. Numerous evidence suggests that overexpression of KDM4 demethylase is involved in breast, prostate, lymphoma, gastric, lung, bladder, medulloblastomas, and colorectal cancers, whereas mutational deletion or knockdown of KDM4A/B/C inhibits cancer cell proliferation and growth [133, 144-146]. The KDM5 family contains KDM5A, KDM5B, KDM5C, and KDM5D. This enzyme removes the methylation marks on H3K4me_{2/3} [132]. KDM5s are also implicated in cancer development. KDMs are either overexpressed (KDM5A) or downregulated (KDM3B) in breast cancers [147]. Differences in KDMs have been shown to be associated with aberrant histone methylation and demethylation of H3K4 and shorter relapse free survival [147]. The abundance of methyl moieties on the lysine residue determines cancer prognosis. For example, increased H3K4me₂ is found in cancerous cells but not in normal cells, and is a biomarker for tumor recurrence in prostate cancer [148-150]. Overexpression of KDM5A has been observed in lung and gastric cancers [151, 152], while overexpression of KDM5B was detected in bladder, AML, lung, breast, chronic myelogenous leukemia (CML), cervical, renal, metastatic prostate cancer, and testicular cancer [153]. Knockdown of KDM5B by siRNA results in inhibition of cancer growth [153, 154]. The KDM6 subfamily contains KDM6A, KDM6B, and UTY (KDM6C), which all exhibit high levels of catalytic activity on H3K27me_{2/3} [155, 156]. Several oncogenic mutations on KDM6A are observed in the cells of multiple myeloma, renal cell carcinoma, and esophageal squamous cell carcinoma [157, 158]. In addition, KDM6B can activate the tumor suppressor *p16INK4A* and *p14ARF*; hence, any mutation or deregulation in these genes might lead to carcinogenesis [159].

3. HISTONE LYSINE ACETYLATION IN CANCER

In addition to the other post-translational modifications, the physiological roles of N-ε-lysine protein acetylation have been identified in tumorigenesis [160]. Some histone acetylation marks have been associated with compaction of chromatin [161], DNA repair [162], protein stability, and protein-protein interaction [82], and lysine acetylation has emerged as the ubiquitous post-translational modification that is found across the entire proteome [163, 164]. Public repositories such as phosphositeplus database show approximately 15,000 lysine acetylation sites in human cells, with prominent roles in signaling networks [165]. Acetylation was initially identified 45 years ago primarily in histones, but lysine acetylation also occurs in non-histone proteins such as transcription factors, chromatin regulators, cytoplasmic proteins

involved in the regulation of cytoskeleton dynamics, and in proteins involved with energy metabolism and endocytosis [163, 164, 166, 167].

3.1. The Deregulation of Histone Lysine Acetyltransferases in Tumor Proliferation and Metastasis

Access to DNA that is wrapped around histones occurs via post-translational modifications such as lysine acetylation. Approximately 10-20 lysine residues get acetylated per histone by lysine acetyltransferases (KATs), which add an acetyl group to the lysine residue on histone. Acetylation of histone increases the negative charge on DNA, thus facilitating the DNA accessibility to proteins involved in replication, transcription, or DNA repair [168-170]. The most understood set of KATs are GNAT5 (Gcn5-related N-acetyltransferase), PCAF (p300/CBP associated factor), Hat1, Elp3, and Hpa2, all of which are involved in transcription initiation. cAMP response element binding (CREB) protein (CBP) and p300 are the two most abundant KATs, both proteins are regulators of RNA polymerase II-mediated transcription, and are ~300 kDa proteins possessing structural homologues with high sequence similarity [171]. Additionally, both KATs acetylate at multiple sites on each of the four core histones H2A, H2B, H3, and H4, and regulate human growth and development [172]. Inactivation or mutation on either of both KATs leads to abnormal organ development and diseases in humans, while insufficiency in p300 leads to aberrant levels of acetylation in multiple cancers [173-177]. The germ line mutation of CBP results in Rubinstein-Taybi syndrome with increased susceptibility to childhood malignancies [171]. Therefore, it is vital to understand the divergent functions such as specificity and selectivity for lysine residues on core histones in treating the disease that they cause. Constitutive activation of transcription factors are observed in all types of cancers. In particular, acetylation of K9, K14, K18, and K56 of histone H3, and K5, K8, K13, and K16 of histone H4 are strongly involved in transcriptional activation [15, 178]. Histone lysine acetyltransferase is known to play important roles in normal and malignant hematopoiesis by acetylating histone and non-histone proteins. In normal hematopoietic stem/progenitor cells, myeloid progenitor cells, and lymphoid cells, protein acetylation by KATs such as p300/CBP, MOZ, HBO1, and GCN5 regulates hematopoietic stem cell (HSC) self-renewal, proliferation, and their differentiation into committed hematopoietic progenitors [179]. Several studies have identified aberrant KAT activity on oncogenes and tumor suppressor proteins that have been shown to be involved in the development of hematological malignancies. In AML, T-cell leukemia, lymphoma, B-cell ALL, and CML leukemogenic proteins physically interact with the KATs p300/CBP, PCAF, MOZ, Tip60, and GCN5, and target cell cycle genes, oncogenes, and tumor suppressor genes such as *Id1*, *p21*, *Egr1*, *c-Myc*, *p53*, *p53*, *RAR β* , *PU.1*, *Syk*, *Btk*, and *AML1* that promote malignant transformation of cells [179]. Over a dozen human lysine acetyltransferases have been identified. Two noted KATs are MOZ (monocytic leukemia zinc finger protein; a.k.a. MYST3 and KAT6A) and its paralog MORF (a.k.a. MYST4 and KAT6B) form tetrameric complexes with BRPF1 (bromodomain- and PHD finger-containing protein 1) and two small non-catalytic subunits. These two acetyltransferases and BRPF1 are found to be recurrently mutated in leukemia, non-hematologic malignancies, and in multiple developmental disorders. The BRPF1 gene is mutated in childhood leukemia and adult medulloblastoma [180]. In addition to hematologic malignancies, the MOZ and MORF gene is mutated in esophageal adenocarcinoma [181] and

metastatic medulloblastoma [182]. The MORF gene is altered in leiomyomata [183, 184], breast cancer [185], and castration-resistant prostate cancer [186]. Moreover, both the MOZ and MORF genes have been identified as very common KATs amplified in different types of cancers [187], suggesting that they have an oncogenic role. Deletion of CBP/p300 specifically reduces acetylation on H3K18ac and H3K27ac in mouse embryonic fibroblasts [188]. Mice heterozygous for CBP spontaneously develop myelodysplastic and/or myeloproliferative tumors [189]. Genetic mutations/deletions of CBP/p300 are correlated with the development of transitional cell bladder cancer [190], follicular lymphoma, and DLBCL [191], relapsed ALL [192] and colon cancer [193]. Overexpression of CBP/p300 is a poor prognostic indicator in small-cell lung cancer [194], and is associated with higher grade tumor with distant metastasis of nasopharyngeal tumor [195]. In melanoma patients, decreased expression of p300 is associated with poor prognosis [196]. CBP/p300 can also induce tumorigenesis independently by acetylating S-phase kinase associated protein 2 (Skp2) [197]. Reduced expression of Tip60 is an indicator for poor prognosis in primary and metastatic melanoma patients [198], and it is also downregulated in colon, lung, head and neck carcinoma, metastatic prostate cancer, and lymphoma [199-204]. In hormone refractory or androgen independent prostate cancer, Tip60 accumulates in the nucleus [202]. In castration resistant prostate cancer LNCaP derived CxR cells; Tip60 is upregulated in the nucleus, which results in the activation of transcription even in the absence of androgen [205]. ER α and PRs have been implicated in breast cancer initiation and progression, and increased activation of ER α is a risk factor for the development of breast cancer by increasing cell proliferation and growth of abnormal breast tissue. ER α is a transcription factor that is activated by hormonal and growth factor signals. Several reports have highlighted the importance of ER α post-translational modification. It has been shown that ER α is acetylated by co-activator p300 at lysine in the hinge/ligand domain at K229, K299, K302, and K303 [206]. In atypical breast hyperplasia samples, lysine to arginine substitution was found at residue K303R in ER α , with increased estradiol dependent activation [207]. Another study demonstrated that, in the presence of p160 and p300 co-activators, ER α was acetylated at K266 and K268 [208]. In breast cancer cells where the tumor suppressor gene BRCA1 is mutated, p300/CBP acetylates ER α and drives cell proliferation, while reintroduction of BRCA1 downregulates p300 and not CBP [209]. Prostate cancer is one of the most frequently diagnosed cancers in men and a leading cause of death worldwide [210, 211]. The androgen receptor (AR) plays a crucial role in prostate cancer growth and progression, and mutations in the AR often lead to tumors becoming resistant to androgen ablation therapy [212]. Post-translational modifications of the AR result in enhanced activity. The AR is acetylated in response to dehydrotestosterone. The AR is acetylated at a conserved lysine residue at K630, K632, and K633, which increases its transcriptional activity [213-217]. It was found that a gain of function mutation increased cell proliferation and colony size in soft agar, and accelerated prostate tumor growth *in vivo* [214]. Histone acetylation was detected in prostate cancer patient tumors and was a positive predictor for tumor recurrence [218]. Deacetylation of ER α and AR by SIRT1 inactivates both the receptors' activity, and thus serves as an alternative approach in the prevention and therapy of breast and prostate cancer [212]. Oncogenic KATs p300 and TIP60 acetylate the AR in a ligand-independent manner and induce transcription of target genes involved in cell proliferation, metastasis, and apoptosis [173, 219]. In resected prostate cancer patients treated with endocrine therapy, p300 and CBP expression is increased. Inhibition of p300 but not CBP using targeted siRNA showed a significant decrease in proliferation rate and

a significant increase in the induction of apoptosis [173]. This might explain why p300 is upregulated in highly metastatic prostate cancer and is an indicator of poor prognosis.

3.2. The Deregulation of Histone Lysine Deacetylases (KDACs) in Cancer

Addition or removal of the acetyl group is catalyzed by acetylases and deacetylases respectively. Aberrant expression due to mutation or deletions of various KDACs is commonly encountered in chronic inflammation associated diseases, in particular cancer. Thus, KDACs are an attractive target for cancer therapy. Numerous studies have indicated global histone acetylation is deregulated in human cancers, and absence of the acetylation mark in H4K16 and H4K20 is critical in establishing the tumor phenotype [220]. The KDACs family of enzymes is divided into four classes and 18 members, based on their sequence homology to yeast KDAC [221, 222]. KDACs deacetylate the acetyl moiety on lysines and thereby can interact with numerous transcription factors to regulate a large number of genes [221]. KDACs are transcriptional repressors because they condense the chromosomes and make them less accessible to transcription initiation [223]. Class 1 KDAC1, 2, 3, and 8 are large protein complexes that silence genes by removing the acetyl moiety on lysine residues on histone tails. High expression of KDAC1, 2, and 3 is seen in urothelial bladder cancer [224]; it is also associated with shorter survival of colorectal cancer patients, and is highly expressed in prostate cancer. Interestingly, KDAC2 is the single prognostic factor that is associated with shorter prostate-specific antigen relapse time following radical prostatectomy [225]. In pancreatic cancers, this class of KDAC is associated with dedifferentiation and rapid proliferation of cells [226-228]. KDAC1 was found to be overexpressed in several organ specific cancers such as gastric, HCC, lung, prostate, breast, and pancreatic cancer samples derived from patients and is a predictor of poor prognosis [228, 229]. Other studies have also reported the overexpression of KDAC1, 2, and 3 in renal cell carcinoma, gastric cancer, and Hodgkin's lymphoma [228, 230, 231]. KDAC8 overexpression is associated with high grade tumor and poor overall survival in childhood neuroblastoma [232]. In a different study analyzing breast tumors, KDAC1 and KDAC3 expression correlates with ER and PR expression, pointing to KDAC1 as an independent prognostic marker [233]. In a tissue microarray representing 44 categories of malignant and borderline mesenchymal tumors, KDAC2 was highly expressed compared to KDAC1, indicating that KDAC2 more likely contributes to the pathogenesis of the disease [234]. KDAC2 is also aberrantly expressed in lung cancer tissues [235]. Class II KDACs are sub-divided into two groups: class IIa consists of KDAC4, KDAC5, KDAC7, and KDAC9; and class IIb consists of KDAC6 and KDAC10. Numerous studies both *in vitro* and *in vivo* have established an association between class IIa KDAC expression and tumor development. KDAC4 is overexpressed in Walsdenstrom's macroglobulinemia [236], breast, renal, and colorectal cancer [237]. In addition, KDAC4 dysfunction is also implicated in cancer development. For example, KDAC4 homozygous deletion was observed in melanoma cells [238], and KDAC4 mutations have also been observed in breast cancer [239]. In renal cell carcinoma, KDAC4 is associated with repression of *Pax7* and regulates HIF1 α transcriptional activity. KDAC5 and KDAC9 are overexpressed and are poor prognostic indicators in medulloblastoma patients, demonstrating an intricate relationship in their expression and poor survival [240]. KDAC5 and KDAC3 overexpression is correlated with copy number gains in hepatocellular carcinoma [241]. In colorectal cancer, KDAC5 and KDAC7 are overexpressed

and interact with the transcription factor GATA-1 [226, 227]. In pancreatic cancer, KDAC7 is overexpressed [242, 243]. In ALL, high levels of KDAC7 and KDAC9 are associated with poor prognosis [244]. In contrast, KDAC7 is not overexpressed in breast, renal, and bladder cancer, and myeloproliferative neoplasms [245]. KDAC9 has been reported to be overexpressed in cervical cancer [246], whereas in glioblastoma, KDAC9 is downregulated [247]. Class IIb KDAC6 is overexpressed in breast and oral squamous cell carcinoma [228]. Deacetylation is also catalyzed by another class of enzymes called sirtuins (Class III KDACs). Sirtuins are NAD⁺ dependent enzymes [248-250]. Sirtuins consist of seven members (Sir1-7) homologous to the yeast KDAC silent information regulator 2 (Sir2) that was cloned and characterized in 1984 as a gene required for maintaining silent chromatin in yeast [251].

Table 1. List of synthetic inhibitors of histone lysine deacetylase either approved or undergoing clinical trials

Compound	KDAC targets	Current status	References
Compound 6j and SEN196	SIRT2	Phase II	[439]
Panobinostat (LBH-589)	KDAC1, 2, 3 and 6	FDA approved	[440]
Vorinostat (SAHA)	KDAC1, 2, 3 and 6	FDA approved	[439]
Romidepsin (FK228)	KDAC1, 2, 3 and 8	FDA approved	[439]
Valproic acid	Class I and Class IIa	FDA approved	[438]
Belinostat (PXD101)	KDAC1, 2, and 3	Phase II	[438]
Entinostat (MS275)	KDAC1, 2, 3 and 8	Phase II	[438]
Mocetinostat (MGCD01030)	KDAC1, 2 and 3	Phase II	[438]
Givinostat (ITF2357)	KDACs	Phase II	[438]
Practinostat (SB939)	KDACs	Phase II	[438]
Chidamide (CS055/HBI-8000)	KDACs	Phase II	[438]
Quisinostat (JNJ26481585)	KDACs	Phase II	[438]
CHR-5154	Macrophage targeted KDACs	Phase I	[441]
CUDC-907	KDACs	Phase I	[441]
Abexinostat (PCI-24781)	KDAC1, 2, 3, 6 and 10	Phase II	[438]
Trichostatin A	KDAC1, 2, 3 and 6	Preclinical	[442]

Sirtuins are regulators of various cellular and pathological processes such as cell proliferation and differentiation, cell survival, stress response and DNA damage, genome stability, metabolism, energy homeostasis, organ development, aging, and cancer. Sirtuins are overexpressed in variety of cancers. SIRT1 is upregulated in prostate, acute myeloid leukemia, and colorectal cancer. SIRT3 and SIRT7 are overexpressed in breast cancer whereas SIRT2 is downregulated in gastric cancer and glioma [252, 253]. KDAC11 belongs to the Class 4 KDACs, and it is overexpressed in colon, prostate, breast, and ovarian cancer [254]. In Hodgkin lymphoma, KDAC11 regulates OX40, a mediator of anti-tumor immunity [228]. However, inhibition of KDACs activity by sodium butyrate or trichostatin A induces apoptosis by upregulating pro-apoptotic protein Bad in human glioma T98G, U251MG, and U877MG cells [255]). There are several FDA approved KDACs inhibitors that are used to treat multiple myeloma, hematological malignancies and solid tumors (Table 1).

4. HISTONE ACETYLATION “CODE” AS A DIAGNOSTIC MARKER FOR CANCER PROGRESSION

Heritable epigenetic marks on histones, such as acetylation, methylation, ubiquitination, and phosphorylation, are maintained with high fidelity during cell division. This phenomenon of histone modifications that act in a dependable manner is called the “histone code” [116, 256]. These post-translational modifications present on the histone tail “codes” are decoded by various cellular machinery regulating cellular processes [256]. Histone post-translational modifications have been detected in almost all cancers types. Loss of H4K16 acetylation and H4K20Me3 is one of the hallmarks of cancers [220]. H3K4Me, H3K9Me2, H3K9Me3, and H3Ac were all reduced in prostate cancer compared to normal prostate tissue [150]. Furthermore, a decrease in H3K4Me2, H3K9Me2, and H3K18Ac levels are all biomarkers of lung cancer, kidney cancer, and pancreatic adenocarcinoma [257, 258]. In lung cancer, aberrant hyperacetylation of H4K5 and H4K8 was observed compared to normal lung epithelium, where hypoacetylation was observed [259]. In addition, H4K20Me3 was shown to be a biomarker for early detection of squamous cell carcinoma [259]. Barlesi et al., 2007 showed that low levels of H2AK5Ac indicated poor prognosis in lung cancer patients [260]. Similarly, adenocarcinoma patients with reduced H3K9Ac exhibited better survival [260]. DNA mismatch repair (MMR) is observed in several cancers and is characterized by frequent alterations in simple repetitive DNA sequences, which is a phenomenon called microsatellite instability and plays a role in apoptosis. In a recent review by Guo Min Li et al., 2013, it was reported that the H3K6Me3 histone biomarker plays an important role in the regulation of MMR *in vivo* in hereditary nonpolyposis colorectal cancer or Lynch syndrome [261]. Taken together, these studies show that histone post-translational modifications can serve as biomarkers for the early diagnosis of cancer and as prognostic predictors.

5. EPIGENETIC MODIFICATIONS IN ONCOGENES AND TUMOR SUPPRESSOR GENES

Oncogenes or proto-oncogenes transcribe oncogenic proteins that alter normal cell proliferation to an abnormal and uncontrolled proliferation of transformed cells [262]. Oncogenes were discovered three decades ago and have, over the years, provided valuable information in understanding the genetic landscape of cancers, differentiation, and apoptosis [262]. One of the most commonly encountered oncogenes in cancer is the *Myc* oncogene. *Myc* regulates a complex inflammatory milieu [263] and, upon activation in B cells, it rapidly induces synthesis and release of IL1 β [264]. The pleiotropic effects of oncogenes include creating a pro-tumor microenvironment, and a persistent, constitutive activation of pro-inflammatory transcription factors [262, 265, 266]. To date approximately 20 transforming oncogenes including *Ras*, *Raf*, *Myc*, *c-Src*, *EGFR*, and *HER-2*, and a number of tumor suppressor genes such as *p53*, *VHL*, and *PTEN* are directly implicated in angiogenesis [267-269]. For example, vascular endothelial growth factor production is upregulated in cancer cells expressing a mutant *Ras* oncogene [268]. Global hypomethylation of genomic DNA is one of the main contributors in the development of aggressive cancers by upregulating oncogenes such as *c-Myc* or *h-Ras* [20]. In addition, promoter hypomethylation can also cause activation of

aberrant expression of oncogenes and induce loss of imprinting in some loci. The tumor suppressor gene, *MASPIN* (also known as *SERPINB5*) becomes hypermethylated in breast and prostate cancer cells [270], whereas *MASPIN* is hypomethylated in other tumor types. *MASPIN* hypomethylation and its subsequent expression increases with the degree of dedifferentiation of some types of cancer cells [271, 272]. The *Myc* oncogene is deregulated in most cancers, where it exhibits abnormally high levels of expression. In a recent study by Wasylishen AR et al., 2014, they show that *Myc* signaling is regulated by six lysine residues near the highly conserved *Myc* homology box IV. These lysine residues are important for the negative regulation of *Myc*-induced transformation and tumorigenesis, which may expose novel therapeutic strategies to target *Myc* in cancer [273]. This region has been previously associated with *Myc* acetylation [274, 275].

The Ras small GTPase family of proteins regulates cellular responses to external stimuli by post-translational modifications. Disruptions to these signals through mutations of *Ras* are involved in 90% of pancreatic cancer and 50% of colon cancer. *Ras* has been shown to be acetylated at lysine 104 and is a negative regulatory modification of *Ras* oncogenicity [276]. In hematological malignancies such as AML and ALL, low frequency mutation in the KAT genes leads to poor prognosis in patients [277]. Chromosomal translocations during mitosis and meiosis generate fusion proteins and chimeric proteins with oncogenic potential. In some rare cases, KAT gene translocations form chimeric proteins that retain KAT catalytic activity and bromodomains. For example, this is seen in mixed lineage leukemia (MLL)-CBP [t(11;16)(q23;p13)] or in MLL-p300 [t(11;22)(q23;q13)] fusions [278]. In addition, monocytic leukemia zinc finger protein (MOZ) fusions such as the MOS-CBP [t(8;16)(p11;p13)] or MOZ-p300 [t(8;22)(p11;q13)] are also reported for AML [174, 279, 280]. These fusions are frequently encountered in patients who have been treated with topoisomerase II inhibitors for the treatment of other cancers, and who can develop secondary therapy-related leukemia [280]. Other oncogenic fusions, in particular the most frequent in AMLs, AML1-ETO [t(8;21)(q22;q22)], require p300 mediated acetylation to induce leukemogenesis [281]. This clearly indicates the importance of transcriptional co-activators p300/CBP and their oncogenic role in cancer progression. In another oncogenic fusion between nuclear receptor co-activator TIF2 and MOZ is associated with AML [inv (8)(p11q13)] and recruits CBP to function as an oncoprotein [180, 282, 283]. Indeed, altered expression of the KATs is found in various cancers [237]. Overexpression of p300 is observed in HCC [284], breast cancer [285], prostate cancer [219], and non-small cell lung cancer [286]. In human skin cancer, upregulation of the enzyme ornithine decarboxylase leads to histone H4 acetylation and skin tumor progression [287]. All these studies suggest KATs as being an integral part of carcinogenesis. p300/CBP acetylates lysine residues K372, K373, and K382 at the carboxy terminal of p53. In addition, DNA damage induces acetylation of K320 and K373, which regulates interactions at DNA binding sites of pro-apoptotic genes [288].

Tumor suppressor *p53* is the most extensively studied gene that is mutated in almost all types of cancers [289]. Under normal physiological conditions, *p53* induces cell cycle arrest, induces apoptosis, and upsets other cellular processes such as senescence and differentiation [290]. The frequent post-translation modification observed in *p53* is acetylation by p300 on 5 lysine residues at the C-terminal regulatory region [291]. Acetylation of *p53* is triggered by ultraviolet light and ionizing radiation [292]). In addition, the *Ras* oncogene and other stress factors also induce acetylation of *p53* [293]. PCAF acetylates K320, while TIP60 (HIV Tat-interacting protein; 60 kDa) and MOF (males absent on the first)-two members of the MYST

family-acetylated K120 are located within the DNA binding domain of *p53* [294, 295]. K120 acetylation induces apoptotic target genes but with minimal or no effect on cell cycle genes. Acetylation of *p53* neutralizes the positive charge on lysine and impairs its ability to form hydrogen bonds. Acetylation also regulates both loss of function and gain of function such as enhancing DNA binding [296] and preventing nonspecific DNA binding by the *p53* C-terminal domain [297]. In addition, acetylation forms docking sites for transcription co-activators, where K382 increases *p53* affinity to CBP bromodomain [298, 299] whereas deacetylation of K373 and K382 enables interaction with the tandem bromodomains of TAF1, a TFIID subunit [299]. Acetylation of *p53* blocks ubiquitination and K320 acetylation but PCAF prevents ubiquitination by E4F1 [300]. Remarkably, both acetylation and ubiquitination activate *p53*. Ubiquitination of K370, K372, K373, K381, and K382 indicates *p53* nuclear export and proteasomal degradation [296]. Thereby, acetylation of these residues stabilizes *p53* and promotes its nuclear localization. Interestingly, in human cancer, p300 and PCAF acetylation sites are not mutated, except K120 which is mutated in human cancer and is linked with cell cycle control and apoptosis [290, 294, 295, 301]. PC4 is a transcriptional coactivator that is acetylated by p300. PC4 interacts with *p53*, and both proteins become acetylated, which enhance their DNA binding ability and leads to the expression of *p53* responsive genes, especially during DNA damage [302, 303].

p53 is also methylated at lysine residues [304]. Lysine mono-methylation of *p53* at K372 by protein lysine methyl transferase (PKMT) and NSD1 regulates its stability and transcriptional activity [305]. This methylation pattern is restricted to the nucleus and is not seen in any of the cytosolic fractions [305]. Subsequently, Huang et al., 2006, showed that PKMT SMYD2 methylates *p53* at K370 and impairs the expression of *CDKN1A* [306]. Inhibiting SMYD2 by small interfering RNA activates *p53*-mediated apoptosis of cancer cells [306]. Interestingly, mono- or di-methylation at K370 of *p53* has contrasting functions. Mono-methylation results in repression of *p53* activity, whereas di-methylation increases the association of *p53* with the co-activator tandem tudor domain containing the *p53*-binding protein1 [126]. LSD1 preferentially demethylates di-methylated *p53* at K370 [126]. The complex nature of methylation or demethylation by SYMD2 or LSD1 respectively can promote oncogenesis, as evidenced by the overexpression of both the enzymes [126]. In another study by Shi et al., 2007, they show that PKMT SETD8 monomethylates *p53* at K382 and suppresses *p53* transcriptional activity in cancer cells [307], indicating that methylation is also an important regulator of *p53* function.

E2F is a family of transcription factors that modulates important cellular events, including cell cycle progression, apoptosis, and DNA damage response, and also functions as a tumor suppressor gene [153, 308]. RB1 is a cell cycle regulator. Both *E2F* and *RB1* genes are exposed to PTMs in several types of cancer [309]. *RB1* is methylated at K810 by SMYD2, which has been identified as being pivotal for cell cycle regulation [310-312]. Methylated *RB1* subsequently enhances phosphorylation of serine 807 and 811 [312]. Unmethylated *RB1* is a suppressor of *E2F* transcriptional activities but, upon RB1 methylation at K810, it transactivates E2F transcriptional activity, and promotes RB1 phosphorylation and cell cycle progression. Furthermore, MYPT1 K442 is a target for methylation. Demethylation of MYPT1 by SETD7 and LSD1 enhances polyubiquitination and subsequent degradation [313], and thereby releases E2F, which transcribes genes that are involved in S-phase to promote cell cycle progression [313]. Taken together, methylation and demethylation regulates cell cycle progression by modulation RB1 activity. Deregulated *E2F* has been detected in a variety of

human cancers [308]. In p53 deficient cells, methylation of K185 or E2F1 by SETD7 induces polyubiquitination and degradation of E2F1, and thus prevents E2F1 accumulation upon DNA damage [314]. In addition, LSD1 also demethylates *E2F1* at K185 and maintains an adequate amount of unmethylated *E2F1* in cancer cells [314].

6. EPIGENETIC MODIFICATIONS IN CELLULAR SIGNALING PATHWAYS

6.1. NF- κ B Signaling Pathway

The master transcription factor NF- κ B was first discovered by David Baltimore in 1986. It is present in the cytoplasm in a heterodimeric form bound to its inhibitor, and upon phosphorylation of its inhibitor, NF- κ B translocates to the nucleus of the cell and binds to the promoter region in the immunoglobulin kappa chain in B cells [315]. NF- κ B regulates multiple biological functions, including inflammation, immunity, cell proliferation, and apoptosis [316]. NF- κ B is activated by many diverse agents such as interleukins, cytokines, T and B-cell mitogens, gram negative bacterial lipopolysaccharide, viruses and viral proteins, double-stranded DNA, and chemical and physical stress [317-319]. NF- κ B regulates more than 400 genes involved in inflammation, immunoregulation, tumor cell proliferation, invasion, metastasis and angiogenesis, chemoresistance and radioresistance [320-322]. Activation of an inflammatory response is mainly mediated through NF- κ B, which is susceptible to post-translational modifications such as acetylation, lysine methylation, and arginine methylation, in addition to its primary phosphorylation modification [323]. Acetylation modification has been shown to be a major player in inflammatory gene expression [324] in T-cells and monocytes [325-327]. Acetylation occurs in the lysine residue of RelA, which regulates NF- κ B transcription activation, DNA binding affinity, I κ B- α assembly, and subcellular localization [328, 329]. Inhibitory kappa kinase (IKK α), in association with polymerase II and CREB binding protein (CBP), binds to the NF- κ B dependent promoter, where it acetylates H3K9 [330] and also phosphorylates H3Ser10 [331]. This IKK α -dependent and cytokine-mediated phosphorylation is essential for CBP-mediated acetylation of H3K14 [332]. One of the common features in cytokine-mediated inflammation and in autocrine and paracrine activation is that it leads to increased NF- κ B driven inflammatory gene expression [333]. However, glucocorticoids and KDAC2 can reverse NF- κ B activation and thus the inflammatory reaction [334]. Poly (ADP-ribose) polymerase -1 (PARP-1), in association with NF- κ B, contributes to the progression of chronic inflammation driven diseases [335]. PARP-1 is a promoter-specific co-activator of NF- κ B *in vivo* and is independent of its enzymatic activity [336]. PARP-1 directly interacts with p300, p50, and p65, and synergistically activates NF- κ B [337]. Under inflammatory conditions, p300 can acetylate PARP-1 at specific lysine residues in a variety of cell types. NF- κ B mediated H3 and H4 acetylation induced by IL1 β , TNF α , or endotoxins can induce the production of granulocyte colony stimulation factor (GM-CSF) [338]. Thus, it is obvious that reversible acetylation of NF- κ B, PARP1, and histones plays a prominent role in regulating gene expression during inflammation. Another important post-translational modification is methylation. An altered lysine methylation pattern is often

observed during inflammatory diseases. The H3K4 methyltransferase SET7/9 can also regulate NF- κ B(p65) to its promoters, thereby activating inflammatory gene expression [339]. In addition, arginine methyltransferases PRMT1 and PRMT4 are transcriptional co-activators of NF- κ B, although they have not been directly implicated in inflammation [340-342]. Recent studies have implicated NF- κ B hyperactivity upon deletion of H3K9 methyl marks from its promoter region, especially in hyperglycemic memory [343, 344], suggesting a strong link between epigenetic modification and NF- κ B in the development of chronic inflammation-driven disease [345, 346]. Constitutive activation of transcription factors is observed in all types of cancers. In particular, acetylation of K9, K14, K18, and K56 of histone H3, and acetylation of K5, K8, K13, and K16 of histone H4 are strongly involved in transcriptional activation [15, 178]. The master transcription factor NF- κ B is another non-histone protein and a key regulator of the cellular immune response that is also regulated by reversible acetylation at K218, K221, and K310. Acetylation of NF- κ B regulates different functions such as DNA binding affinity, I κ B α assembly and subcellular localization, and in the recruitment of NF- κ B co-activators such as BRD4 and PTEFB [347], which stimulates the transcription of NF- κ B target genes. In turn, acetylated NF- κ B is deacetylated by KDAC3 [348]. Acetylated NF- κ B and its subsequent recruitment of bromodomain-containing factor Brd4, which is a member of the bromodomain extraterminal (BET) family, leads to sustained activation of NF- κ B in adult T-cell leukemia [349]. Acetylation of p65 at K122 and K123 reduces its affinity for DNA and increases I κ B interaction, while suppressing downstream gene expression [350]. In addition, acetylation of p50 at K431, K440, and K441 enhances transcriptional activation [351]. In breast cancer, the ER along with NF- κ B plays an important role in cell proliferation and survival. Pradhan et al., 2012 show that there is a major increase in NF- κ B dependent histone acetylation around the estrogen response element in the BIRC3 promoter region in aggressive luminal B breast tumors [352], which is in contrast to earlier reports that suggested repressive interactions between ER and NF- κ B [352].

The importance of protein lysine methylation in the pathogenesis of cancer is broadly divided into 5 categories. First, lysine methylation affects other post-translational modifications directly or indirectly. Second, lysine methylation regulates protein-protein interaction. Third, lysine methylation inhibits polyubiquitination of lysine residues. Fourth, lysine methylation regulates subcellular localization of proteins. Fifth, lysine methylation regulates promoter binding affinity of transcription factors, thereby controlling the expression levels of target genes [353, 354]. Lysine di-methylation of RelA by PKMT and NSD1 increases its promoter binding ability and transcriptional activity [88, 135, 355]. Upon TNF α stimulation, SETD7 methylates K37 RelA in the nucleus and increases the promoter binding affinity of RelA. Lu et al., 2013 reported that NSD1 methylates RelA at two sites, K218me1 and K221me2, to increase NF- κ B transcription of target genes, while any mutations on these two sites diminish its ability to initiate transcription [355]. In addition, SETD6 methylates RelA at K310 in primary immune cells and completely abolishes the NF- κ B mediated inflammatory response [356]. RelA methylation is demethylated by PKDM F-box and leucine-rich repeat protein 11 (FBXL11). Overexpression of FBXL11 inhibits NF- κ B activation and impedes the growth of HT29 colon cancer cells [135]. Yang et al., 2012 found that, in castration-resistance prostate cancer, NSD2 interacts with NF- κ B and acetyltransferase p300 and di or tri-methylates H3K36 at the

promoter regions of NF- κ B target genes [357]. Overall, transcriptional activation or inhibition of NF- κ B is intricately linked to the site of methylation on RelA.

6.2. STAT3 Signaling Cascade

Signal transducer and activator of transcription (STAT) is another important transcription factor that is constitutively activated in cancer cells. The primary route of signaling in the STAT signaling pathway is via cytokine ligand-induced receptor dimerization, which activates receptor-associated tyrosine kinases and in-turn phosphorylates STATs, induces dimerization, nuclear translocation, DNA binding, and cytokine responsive genes [358]. Acetylation of STAT3 is a cytokine-induced, post-translational modification. STAT1, STAT2, STAT3, STAT5, and STAT6 have been shown to be acetylated by CBP/p300 [359]. Of all the STAT family of transcription factors, the most prominent is STAT3. STAT3 gets acetylated by histone acetyl transferase CBP/p300 at K685. Acetylation enhances its DNA binding affinity, increases transcriptional activation, promotes protein–protein interaction, and modulates dimerization [360]. Deacetylation by KDAC3, and to a lesser extent by KDAC1 and KDAC2, can lead to loss of DNA binding and suppression of transcription [360]. Thus, the acetylation and deacetylation reaction is a novel signaling mechanism that regulates the IL6/STAT3 signaling pathway in hepatocellular carcinoma. In addition to K685 acetylation, STAT3 also gets acetylated by p300 on aa49 and aa87 at its NH2 terminal domain, but the exact role of this in transcriptional initiation is still unclear [361]. When lysine residues were substituted by arginine at K679, K685, and K707, it reduced STAT3 phosphorylation compared to a K685R mutant alone, signifying the importance of the regulatory role of multiple acetylations [362].

In another report by Ohbayashi et al., 2007, they showed that IL-6 or leukemia inhibitory factor induced acetylation of STAT3 at K685 in 293T and Hep3B cells. This effect was abolished by the PI3K inhibitor, LY294002 [363]. STAT1 also gets acetylated and binds to the NF- κ B subunit p65, and negatively regulates NF- κ B target genes in cancer cells [364]. In the majority of published studies, cytokines have been shown to be the major inducers of acetylation; however, KDAC inhibitors have also been shown to hyperacetylate STAT3. In diffuse, large B-cell lymphoma (DLBCL), the KDAC inhibitor LBH589 leads to STAT3 hyperacetylation and dephosphorylation, and thereby inhibiting STAT3 transcription in DLBCL cells [365]. Acetylation of the transcription factor E2F1, which regulates cell cycle progression, at the N-terminal promotes DNA binding activity [366, 367] while acetylation attenuates Foxo1 and p65 transcription factors' ability to bind to DNA [350, 368]. The innate immune response activated by toll like receptors (TLRs) upon exposure to lipopolysaccharide often leads to chronic inflammation. Stimulation of TLRs induces expression of mitogen activated protein kinase (MAPK) phosphatase-1 (MKP1), which is acetylated at a key lysine residue K57, and promotes the dephosphorylation of p38MAPK and c-jun N-terminal kinase (JNK), resulting in the attenuated production of pro-inflammatory cytokines [369]. STAT3 is a latent transcription factor that is constitutively activated in numerous cancer cells [370]. STAT3 is di-methylated by SETD7 at K140 following phosphorylation, dimerization, nuclear translocation, and promoter binding; however, this reversible methylation is demethylated by LSD1 [371]. This transient dimethylation has a minimal repressive effect and contributes to specific transcriptional regulation. Furthermore, STAT3 is trimethylated at K180 by EZH2,

which increases the phosphorylation of STAT3 in glioblastoma cells [372]. Interestingly, inhibiting EZH2 directly inhibits Polycomb gene expression and indirectly blocks STAT3 activation, which serves as a strategic target for glioblastoma therapy.

6.3. Wnt/ β -Catenin Signaling Pathway

The Wnt signaling pathway is evolutionarily conserved and plays important roles in the development of organ systems. The important mediators in this pathway are adenomatous polyposis coli (APC), glycogen synthase kinase 3 β (GSK3 β), axin, and the transcriptional cofactor β -catenin (encoded by *CTNNB1*) [373]. Under normal circumstances, β -catenin levels remain low due to constitutive phosphorylation of β -catenin by GSK3 β and subsequent polyubiquitination and degradation of β -catenin [374]. Wnt ligand binding to the frizzled (Fz) receptor activates the Disheveled (Dvl) adaptor protein, which in turn inhibits GSK3 β activity and thereby inhibits β -catenin degradation. β -catenin translocates to the nucleus where it binds to the T-cell factor (Tcf)/lymphoid-enhancing factor (Lef) family of transcription factors and induces the expression of genes such as *CMYC* and *CCND1* [375]. A high level of nuclear β -catenin is often observed in a variety of cancers [374]. Aberrant Wnt signaling is a very common phenomenon in colon and hepatocellular carcinoma [376]. Epigenetic silencing of genes involved in Wnt signaling (by DNA methylation), and histone modification in tumor suppressor genes is a major contributor in aberrant Wnt/ β -catenin signaling in cancers [377]. Promoter hypermethylation of Wnt inhibitors such as secreted frizzled-related protein (SFRP), Wnt inhibitory factor 1 (WIF1), HDPR1, and Dickkopf 3 (DKK3) is seen in a variety of tumors [378-380]. Schiefer et al., 2014 recently demonstrated that hypermethylation of the SFRP family was a common feature of human glioblastoma multiforme [381].

Overexpression of Wnt1, 2, 3A, and 5A leads to oncogenic activation of canonical Wnt signaling in cancers of the breast, colon, lung, and prostate [382, 383]. Wnt5A, a tumor suppressor, is silenced by methylation in hematological malignancies. Inactivation of Wnt7A and Wnt9A by promoter hypermethylation has been reported in ALL, pancreatic, and colon cancer [384, 385]. Promoter hypermethylation of SFRP1 and WIF1 is a poor prognostic indicator in breast cancer and acute promyelocytic leukemia respectively [386-388]. In gastric cancer, DKK3 hypermethylation is strongly correlated with a shorter survival time for patients [389]. Epigenetic silencing of *CDH1* and *APC* by promoter methylation leads to aberrant activation of Wnt/ β -catenin signaling in invasive ductal carcinoma of the breast [390]. NSD2 methyltransferase may activate the Wnt signaling pathway through interaction with β -catenin [391]. NSD2 was shown to interact with β -catenin and its co-activators IQ motif containing GTPase activating protein 1 (IQGAP1) and T-cell lymphoma invasion and metastasis 1 (TIAM1) proteins and increase motility, adhesion, and migration properties [88]. Inhibiting NSD2 concomitantly decreases the expression of cyclin D1 (*CCND1*), a target of the β -catenin/Tcf4 complex, through H3K39 trimethylation [88]. Interestingly, Ge et al., 2009 reported that PCAF acetylation stabilizes β -catenin in colon cancer cells [392].

7. EPIGENETIC MODIFICATION IN CANCER STEM CELLS

Cancer stem cells (CSCs) represent a small sub-population in the whole tumor population that represents the tumor initiating clone. They are very similar to normal stem cells in that they have unlimited self-renewal capacities with the potential to differentiate into many cancer cell types. CSCs are resistant to chemotherapy and may be responsible for the distant site metastasis of cancers [393, 394]. EZH2 catalyzes methylation of histone H3K27me₃ to cause the silencing of tumor suppressor genes [395, 396]. Extensive reports have shown that EZH2 plays a critical role in cancer initiation, progression, and metastasis, and also in cancer stem cell biology [102, 397]. EZH2 plays a pivotal role in the maintenance and self-renewal of embryonic and adult stem cells [398–400]. EZH2 has been implicated in the maintenance of CSC, promotion of breast cancer progression [401], and glioblastoma CSC self-renewal and progression [402, 403]. In hematological malignancies, DNA hypermethylation by DNMTs of oncogenic pathway regulatory genes may contribute to the differentiation of hematopoietic stem cells to leukemia stem cells (LSCs) and leukemogenesis [51, 52, 404–406].

Activating mutations of the DNMT3A gene is a poor prognosis indicator in AML, with leukemogenic mutations of Flt3-ITD, NPM1, PTPN11, and IDH2 genes being associated with intermediate risk [407]. In addition, other mechanisms mediated by KDMs and KATs play key roles in the development and maintenance of LSCs [52]. In AML-CSCs and non-CSCs there is a difference in the histone methylation pattern, especially in H3K4me₃ and H3K27me₃, whereas it is the same in DNA methylation patterns [408]. In glioblastoma multiforme (GBM)-CSCs, the loss of polycomb mark H3K27me₃ from the promoters is the primary cause for the activation of multiple transcription factors [409]. In particular, activation of the achaetescute complex homolog-like 1 (Ascl1) transcription factor causes activation of the Wnt signaling pathway, which is required for the maintenance of stemness and its tumorigenicity [410, 411].

8. EPIGENETIC MODIFICATIONS ASSOCIATED WITH CANCER CHEMO- AND RADIO-RESISTANCE

Epigenetic alterations are now increasingly recognized as major factors in tumor biology and are integral for their role in treatment resistance. Epigenetic modulators have made a profound impact in preventing, delaying, or reversing chemo-resistance, as seen with the use of natural product molecules or synthetic molecules that can reverse DNA methylation or histone deacetylation [412, 413]. The emergence of a CSC population is now recognized as one of the causative factors contributing to multi-therapy resistance, which is further compounded by new mutations arising in genes associated with oncogenic signaling pathways [414–416]. For example, *K-Ras* mutation in multiple tumor types, *APC* in colon cancer, and *VHL* in renal cancer empower the cancer cells with self-renewal and tumorigenic properties [25]. CBP/p300 is implicated in resistance in certain cancer types. P300 expression is reduced in doxorubicin-resistant bladder cancer cells and knockdown of p300 leads to bladder cancer cells being resistant to doxorubicin [417].

In addition, CBP/p300 is required in the interleukin-4-mediated castration resistance of prostate cancer cells. Downregulation of CBP/p300 abolished interleukin-4-mediated AR activation [418]. Overall, the changes in genetic alterations, expression level, and subcellular

localization of CBP/ p300 are associated with progression, prognosis, and resistance of many types of cancers. Acquired drug resistance is the most common phenomenon in cancer therapy [419].

Overexpression of the hMLH1 DNA mismatch repair enzyme in ovarian cancer confers resistance to platinum drugs; 25% of patients acquired hMLH1 methylation during chemotherapy, and hMLH1 methylation is poor prognosis indicator [420].

Treatment with the DNMT inhibitor azacitidine reactivates hMLH1, reverses resistance [421, 422], and sensitizes ovarian cancer cells to platinum drugs *in vitro* [423]. The methylation status of the cells serves as a biomarker to monitor progression in patients under treatment with platinum drugs [413, 424, 425]. KAT Tip60 is overexpressed in cisplatin-resistant human lung cancer cells, and knockdown of Tip60 expression sensitizes the cells to cisplatin therapy [426]. ABCB1 (MDR1) is a multidrug resistance p-glycoprotein that is often induced in traditional chemotherapy. However, upon chemotherapy, hypermethylated promoter regions decrease in these cells while, in contrast, epigenetic methylation is implicated in the development of multidrug resistance [427, 428]. These findings suggest that epigenetic methylation independently could contribute to multidrug resistance and not as a part of accumulating genetic mutations in cancer development. In cisplatin resistant ovarian cancer cells, KDAC4 is overexpressed and promotes cancer cell survival by deacetylating the transcription factor STAT1 [429]. The promoter methylation-specific silencing of gene O-6-methylguanine-DNA methyltransferase (*MGMT*) in glioma serves as a biomarker to the alkylating agent carmustine or temozolomide [430-433]. Romidepsin, a KDAC inhibitor, increases sensitivity to EGFR tyrosine kinase inhibitors in lung cancer [434]. In a combination therapy with the KDAC inhibitors entinostat and erlotinib, patients experienced disease progression due to erlotinib resistance that was due to epigenetic changes [435]. In another combination therapy, all-trans-retinoic acid with the LSD1/KDM1A inhibitor tranylcypromine has been shown to upregulate the myeloid differentiation pathway [129, 436, 437].

9. PHARMACOLOGICAL INHIBITORS OF EPIGENETIC MODIFICATIONS

Especially in malignant epithelial and hematological tumors, deregulation of cellular signaling pathways is often due to overexpression of epigenetic modifying enzymes that either methylate or acetylate the DNA or the lysine residues on the histone. KDAC inhibitors are classified into groups based on their chemical structure, including hydroxamic acids (trichostatin A, vorinostat), carboxylic acids (valproate, butyrate), aminobenzamides (entinostat, mocetinostat), cyclic peptides (apicidin, romidepsin), epoxyketones (trapoxins), and hybrid molecules [438]. Table 1 lists the KDAC inhibitors that have been approved by the FDA and the other drugs that are in clinical trials for the treatment of cancers. Table 2 depicts the DNA methyltransferase inhibitors that are in clinical trials. Table 3 indicates the histone methyltransferase and histone demethylase inhibitors currently undergoing clinical trials. The histone acetyl transferase inhibitors currently in use are presented in Table 4.

Table 2. A list of selected pharmacological DNA methyltransferase inhibitors

Compound	Mechanism(s) of action	Current status	Reference
5-Azacytidine (Vidaza)	Nucleoside DNMT inhibitor	FDA approved	[441]
Decitabine (Dacogen)	Nucleoside DNMT inhibitor	FDA approved	
5-fluor-2'-deoxycytidine (FdCyd) with tetrahydrouridine (THU)	FdCyd metabolite inhibits DNMT	In Phase I and Phase II clinical trials	
ASTX-727	Nucleoside DNMT inhibitor	In phase I clinical trials	
CC-486	Nucleoside DNMT inhibitor	In phase I-III clinical trials	
Hydralazine	Non-nucleoside DNMT inhibitor	In Phase I-III clinical trials	
MG-98	Non-nucleoside DNMT inhibitor	In phase I clinical trials	
RRx-001	Non-nucleoside DNMT inhibitor	In Phase I and phase II clinical trials	
SGI-110	Nucleoside DNMT inhibitor	In phase I and Phase II clinical trials	
Zebularine	Nucleoside DNMT inhibitor	Preclinical	
SGI-1027	Non-nucleoside DNMT inhibitor	Preclinical	
RG108	Non-nucleoside DNMT inhibitor	Preclinical	
Psammaplin A	Non-nucleoside DNMT inhibitor	Preclinical	
Procain and procainamide	Non-nucleoside DNMT inhibitor	Preclinical	
CP-4200	Nucleoside DNMT inhibitor	Preclinical	
Epigallocatechin-3-gallate	Nucleoside DNMT inhibitor	Preclinical	

Table 3. A list of selected Histone lysine methyl transferase (KMTi) and histone lysine demethylase inhibitors (KDMi)

Compound	Target	Reference
Chaetocin	KMTi	[442]
DZNep	KMTi	
BIX-01294	KMTi	
AMI-1	KMTi	
AMI-5	KMTi	
Allantodapsone	KMTi	
RM-65	KMTi	
Tranylcypromine	KMTi	
Pargyline	KMTi	
Phenelzine	KMTi	

Table 4. A list of selected Histone lysine acetyltransferase inhibitors (KATi)

Compound	Target(s)	References
Garcinol	PCAF/p300	[442, 443]
Isogarcinol/LTK14	PCAF/p300	[439, 443]
Curcumin	CBP/p300	[439, 443]
Anacardic acid	PCAF/p300	[439, 443]
Lys-CoA	p300	[439]
Lys-CoA-CH ₃	PCAF	[439]
Ph-Lys-CoA	P300	[439]

PERSPECTIVES AND CONCLUSION

Epigenetic changes such as DNA methylation and histone modification by enzyme DNA methylases, histone lysine methyltransferases, demethylases, histone lysine acetyltransferases and deacetylases control critical gene transcription mechanisms. Their deregulation is often seen in diseases and malignancies. Detailed investigations of the changes that regulate disease progression are essential, and epigenetic alterations constitute valuable therapeutic targets. Large scale screening of the epigenome has helped in identifying several new epigenetic targets that have enormous potential in epigenetic-specific therapy. Several KDAC and DNA methyltransferase inhibitors have been approved by the FDA for the treatment of cancers. While natural product agents have shown significant progress in preclinical studies, well defined human clinical trials are essential to validate their potential as a therapeutic modality. Overall, existing evidence(s) clearly suggest that drugs targeting the epigenome have made significant inroads in cancer therapy, especially in the management of hematological malignancies and in other aggressive solid tumors.
